## Canadä'

#### Abstract

The assessment model formulation for the Eastern Georges Bank (EGB) cod management unit was last established in a benchmark review conducted in 2002. During the 2008 assessment, concerns were expressed about survey catchability and fishery partial recruitment (PR) patterns and the generation of appreciable "cryptic" biomass. A benchmark assessment to address these concerns was conducted in 2009. A further complication was the divergence of assessment approaches and results between the Canada/USA transboundary management unit, 5Zjm and the USA management unit, $5 Z+6$, of which the former is a part.

The background for the delineation of management units of cod on Georges Bank and the vicinity was reviewed. Stock structure, political and administrative boundaries and practical limitations of fishery monitoring and regulation all played a role. Various biological and tagging studies indicate that there is a resident spawning population that occupies eastern Georges Bank but exchanges with cod from the Great South Channel/Nantucket Shoals and stronger exchanges with Browns Bank cod occur. Maintaining the present management units is the least disruptive with respect to the existing agreement for consistent management by Canada and the USA but harmonization of the two assessments (Georges Bank and EGB) is required for this approach.

USA and Canadian catches (landings and discards) for 1978 to 2007 were updated and reviewed. Canadian landings were primarily from otter trawl and longline gear and discards from the groundfish fishery and scallop fishery were included. Almost all USA fisheries landings were taken by otter trawl. A change to the collecting and processing of USA fishery statistics occurred in 1994, going from a voluntary submission of catch quantities by processors and dealers and the use of personal interviews to obtain fishing effort and positional data, to mandatory submission of dealer reports and vessel trip reports (logbooks). Discards were primarily from the USA otter trawl fishery and were included for the years 1987 to 2007 . Size and age composition of catches was obtained using port and at-sea sampling and the standard protocols employed by each country.

The DFO survey, conducted in February/March since 1986, the NMFS autumn, since 1963, and the NMFS spring, since 1968, along with the combined Canada/USA catch at age were used to determine stock status and size and maturity at age.

Investigations of fishery PR and survey trends in abundance and catchability at age from a basic Virtual Population Analysis (VPA) calibration, and total mortality and relative exploitation calculations from survey and fishery catch at age data determined that 1) there was no support for a change to steeply domed fishery PR, 2) there were indications of increased survey catchability for ages 3 or 4-6 in recent years, 3) total mortality declined some in the mid 1990s but remains high, 4) there were indications of higher natural mortality ( $M$ ) for fish 6 years old and older and, 5) the relative exploitation rate had declined in recent years.

A number of VPA model formulations were explored, including splitting the surveys between 1993 and 1994 ("split"), letting the model estimate M and assigning various values for M starting from different ages. Three models were ultimately chosen for comparison of results and diagnostics: 1) no "split" with an M of 0.7 for ages $6+$, 2 ) "split" with constant M of 0.2 , and 3) "split" with M fixed at 0.5 for ages $6+$. Diagnostics used to evaluate each model included: 1) survey catchability $q, 2$ ) population abundance, 3) estimated biomass trend compared with survey biomass trend, 4) population biomass, 5) age patterns in $F, 6$ ) time patterns in $F$ with respect to catch, 7) residual patterns, 8) retrospective pattern, and 9) Akaike Information Criteria (AIC) and Bayesian Information Criteria (BIC). All three models could be supported or criticized.

Model fit diagnostics did not provide convincing selection results among them and there were strong residual patterns no matter which model was used.

The Age Structured Assessment Program (ASAP) forward projection model was run as an exploratory alternative model to the VPA for both EGB and Georges Bank. This model allows for the inclusion of additional catch and survey indices without age composition data and provides more flexibility for weighting of input data and in examining partial recruitment by fleet. The models tested all exhibited retrospective patterns.

There was no strong biological information or knowledge to support large changes of survey $q$ or M although some diagnostic evidence indicated that both survey $q$ and M have changed. Several desirable features were displayed by the "split M 0.5" model. However, it was recommended during the benchmark review meeting that the results from the comparable model "split M 0.2" model also be considered. Until the fate of the 2003 year class has been documented (ages $6+$ ) it will be necessary to use these two models to adequately account for uncertainty in the assessment. Doing so acknowledges that there is considerable uncertainty about selection of a single appropriate model.

It was decided that it may be premature to adjust $F_{\text {ref }}$ because of the uncertainties about fish growth and natural mortality changes and the inability to characterize a stock-recruitment relationship.

Illustrative projections were conducted to evaluate how differences in stock status determination using the various models translated into differences for catch advice and biomass trajectory.

## RÉSUMÉ

La formule actuelle du modèle d'évaluation de l'unité de gestion de la morue de l'Est du banc Georges (EBG) a été établie en 2002, lors d'un examen des points de référence. Au cours de l'évaluation de 2008 ont surgi des questions sur les profils de capturabilité dans le relevé et du recrutement partiel à la pêche ainsi que sur la constitution d'une biomasse cryptique appréciable. Un examen des points de référence a été effectué en 2009 pour tenter de régler ces problèmes. La divergence des approches d'évaluation et des résultats entre l'unité de gestion transfrontalière Canada-États-Unis 5Zjm et l'unité de gestion états-unienne $5 Z+6$, dont fait partie la première, vient encore compliquer la question.

Nous avons examiné le contexte de la délimitation des unités de gestion de la morue sur le banc Georges et aux alentours. La structure des stocks, les frontières politiques et administratives et les limites d'ordre pratique imposées par la surveillance et la réglementation des pêches avaient toutes une incidence. Diverses études biologiques et des travaux de marquage indiquent qu'une population reproductrice résidente occupe l'Est du banc Georges mais que des échanges ont lieu avec la morue du Grand Chenal Sud et des hauts-fonds de Nantucket et, de façon plus marquée, avec celle du banc de Browns. Le maintien des unités de gestion actuelles est l'approche la moins dérangeante au regard de l'entente existante sur la gestion rationnelle des stocks par le Canada et les États-Unis, mais une harmonisation des deux évaluations (banc Georges et EBG) s'impose alors.

Les prises canadiennes et états-uniennes (débarquements et rejets) de la période 1978-2007 ont été actualisées et revues. Les débarquements canadiens provenaient surtout des chalutiers et des palangriers, et on a inclus les rejets de la pêche des poissons de fond et des pétoncles. Presque tous les débarquements de la pêche états-unienne étaient le fait des chalutiers. En

1994, des changements au mode de collecte et de traitement des statistiques de pêche ont été apportés aux États-Unis; au lieu de déclarations volontaires des volumes de captures par les transformateurs et négociants et du recours à des entrevues en personne pour obtenir des données sur l'effort de pêche et la position, il est maintenant obligatoire de soumettre des rapports des négociants et des rapports sur les campagnes de pêche (journaux de bord). Les rejets, qui étaient surtout le fait des chalutiers aux États-Unis, ont été inclus pour la période 1987-2007. La composition des prises selon la taille et l'âge a été obtenue par des échantillonnages au port et en mer, selon les protocoles normalisés de chacun des pays.

Pour déterminer l'état des stocks et la taille et la maturité selon l'âge, on s'est appuyé sur le relevé mené en février-mars par le MPO depuis 1986, et sur les relevés du NMFS effectués à l'automne depuis 1963 et au printemps depuis 1968, ainsi que sur les données combinées Canada-États-Unis sur les captures selon l'âge.

Les examens du recrutement partiel (RP) à la pêche et des tendances de l'abondance et de la capturabilité selon l'âge d'après les relevés, après calibrage de l'analyse de la population virtuelle (APV) de base, ainsi que les calculs de la mortalité totale et de l'exploitation relative à partir des données sur les captures selon l'âge fournies par les relevés et par la pêche, ont permis de déterminer ce qui suit : 1) rien ne justifierait une modification de la courbe en dôme marqué du RP à la pêche; 2) on peut constater une hausse de la capturabilité des âges 3 ou 4-6 dans les relevés des dernières années; 3) la mortalité totale a légèrement baissé au milieu des années 1990 mais demeure élevée; 4) on note des signes de hausse de la mortalité naturelle (M) pour les poissons de 6 ans et plus; 5) le taux d'exploitation relative a baissé ces dernières années.

Diverses formules du modèle d'APV ont été explorées, notamment en fractionnant les relevés entre 1993 et 1994 («fractionnement»), en laissant le modèle estimer $M$ et en attribuant diverses valeurs à M en partant de différents âges. Trois modèles ont finalement été retenus pour la comparaison des résultats et les diagnostics: 1) pas de fractionnement avec une valeur M de 0,7 pour les âges $6+; 2$ ) fractionnement avec M constante de 0,$2 ; 3$ ) fractionnement avec $M$ fixée à 0,5 pour les âges $6+$. Les diagnostics retenus pour évaluer chaque modèle étaient: 1) coefficient de capturabilité ( $q$ ) des relevés; 2 ) abondance de la population; 3) tendance estimée de la biomasse comparée à la tendance de la biomasse d'après les relevés; 4) biomasse de la population, 5) profils des âges dans F; 6) profils chronologiques dans $F$ en ce qui concerne les captures; 7) profils résiduels; 8) profils rétrospectifs; 9) critère d'information d'Akaike (AIC) et critère bayésien d'information (BIC). Chacun des trois modèles peut susciter autant l'adhésion que la critique. Les diagnostics d'ajustement des modèles n'ont pas fourni de résultats convaincants facilitant la sélection, et on notait de forts profils résiduels quel que soit le modèle employé.

On a essayé le modèle à projection prospective du programme d'évaluation à structure d'âge (ASAP) comme solution de rechange exploratoire à l'APV tant pour l'EBG que pour le banc Georges. Ce modèle permet d'inclure des indices supplémentaires des captures et des relevés sans que l'on ait besoin des données sur la composition par âge, et donne plus de souplesse pour pondérer les données d'entrée et pour examiner le recrutement partiel par flottille. Dans tous les cas, les modèles présentaient des profils rétrospectifs.

Aucun apport solide de données biologiques ou de connaissances ne justifierait des changements notables du $q$ des relevés ni de $M$, même si certaines preuves diagnostiques pointent vers une modification dans ces deux paramètres. Plusieurs caractéristiques souhaitables ressortent du modèle fractionnement $+M=0,5$. Toutefois, pendant la réunion sur l'examen des points de référence, il a été recommandé de tenir aussi compte des résultats du
modèle comparable fractionnement $+M=0,2$. Jusqu'au moment où l'on aura documenté le devenir de la classe 2003 (âges 6+), il sera nécessaire d'utiliser ces deux modèles pour rendre compte adéquatement de l'incertitude dans l'évaluation. Cette démarche prend acte de l'incertitude considérable qu'implique le choix d'un seul modèle approprié.

Il a été décidé qu'un ajustement de $\mathrm{F}_{\text {ref }}$ serait prématuré compte tenu des incertitudes relatives aux changements dans la croissance des poissons et la mortalité naturelle et de l'impossibilité de caractériser une relation stock-recrutement.

Des projections à caractère illustratif ont été effectuées pour évaluer en quoi les différences dans l'état des stocks obtenu par les divers modèles se traduisaient par des différences sur le plan des avis de gestion et des tendances de la biomasse.

## INTRODUCTION

Following declaration of exclusive economic zones by coastal states in 1977, cod on Georges Bank have been exploited by only Canadian and USA fisheries. Cod are considered transboundary with respect to the Canada/USA maritime boundary that was established by the International Court of Justice in 1984. The Transboundary Resources Assessment Committee (TRAC) was established in 1998 to conduct joint Canada/USA peer review of assessments for transboundary resources in the Georges Bank/Gulf of Maine area and thus provide a common understanding of resource status. While stock assessment results are needed routinely to serve the management system, it is not practical to evaluate the assessment approach each time the assessment is conducted. The TRAC review process is two tiered, with annual assessment reviews undertaken between more intensive, periodic benchmark reviews. The assessment model formulation for Eastern Georges Bank cod was last established in benchmark review conducted in February 2002 (O'Boyle and Overholtz, 2002).

At the June 2008 assessment meeting, concerns were expressed about the model formulation established by the 2002 benchmark assessment. In recent years the model results exhibit domed catchability for older ages in surveys conducted by both Fisheries and Oceans Canada (DFO) and the USA National Marine Fisheries Service (NMFS), as well as a domed fishery partial recruitment (PR) for older ages, thereby generating 'cryptic' biomass that is not observed in the fishery or the surveys. This could potentially lead to an overestimation of fish at older ages and a benchmark review was recommended.

For the purpose of developing a sharing proposal, agreement was reached that the transboundary management unit for Atlantic cod would be limited to the eastern portion of Georges Bank (DFO Statistical Unit Areas 5Zj and 5Zm; USA Statistical Areas 551, 552, 561 and 562). For USA domestic management purposes, the multi-species management plan treats cod in NAFO Div. $5 Z$ and Subarea 6 as an operational stock unit (Figure 1). At the 2008 USA Northeast Groundfish Assessment Review Meeting(GARM III) (NEFSC 2008), the assessment model for $5 Z+6$ cod was established using a model with split survey time series and natural mortality of 0.2 There is concern that development of fisheries management advice from potentially differing assessment approaches arrived at through independent reviews may make reconciliation of results difficult.

This manuscript documents the supporting analyses that formed the basis of the consensus assessment model formulation reached during the benchmark review conducted in 2009.

## MANAGEMENT UNIT

The previous benchmark assessment reviews of the two operational management units, $5 Z j m$ cod and 5Z+6 cod, were conducted at the same TRAC meeting in 2002 where comparisons for harmony between the results from the two analyses were examined. The basis for the management units was not reviewed at that meeting. This section summarizes the background for the delineation of management units of cod on Georges Bank and the vicinity.

## Management of Cod

A management unit is a geographic area defined for regulatory purposes. Stock is used to mean an identifiable population of a species. A stock complex is a group of stocks of a species. The designation of units for management entails a compromise between the biological realities of stock structure and the practical convenience of analysis and policy making (Gulland 1980).

The recent history of management units employed for cod on Georges Bank and the vicinity is briefly summarized here. From 1973 to 1981 the 'offshore stock' associated with Browns Bank was managed separately (Halliday 1974), but since 1982 all of 4 X has been treated as a management unit due to difficulties in distinguishing catches from the components (Campana and Simon, 1985). Cod in 5Y have been managed separately from cod in $5 Z$ since 1972 (Serchuk and Wigley, 1992). USA and Canada assumed separate responsibilities for management of cod in their respective waters following extension of jurisdiction in 1977. On the basis of demographic similarities (Serchuk and Wood, 1979), $5 Z$ and Subarea 6 have been treated as an operational management unit for cod by the USA since 1977. Canada similarly considered $5 Z$ and Subarea 6 as an operational management unit until a re-examination in 1989 resulted in designation of cod in DFO Statistical Unit Areas 5Zj and 5Zm as a separate management unit (Bowen 1987, Hunt 1989).

## Delineation of Fishing Areas

The delineation of fishing areas for the purpose of collecting and reporting fisheries statistics pre-dates the designation of management units. Halliday and Pinhorn (1990) give a detailed description of the development of fishing area boundaries. Agreement on the first geographically defined areas in the northwest Atlantic was reached in the early 1930s. A finer scale statistical area grid was subsequently developed and has been in use by the USA and Canada since the 1940s. The statistical area grid was principally designed to reflect historically important fishing grounds and the distribution of fisheries.

The primary scientific input to fishing area delineation was information on stock structure. In addition, convenience with respect to political and administrative boundaries and practical limitations of fishery monitoring and regulation also played a role in the delineation of areas. For example, distributions of national fisheries interests in relation to the anticipated national member composition of Panels played a role in the designation of ICNAF Subarea boundaries. Due to the prominence of the haddock fishery at the time that fishing areas were being delineated, there are indications that the placement of statistical area boundaries was strongly influenced by knowledge about haddock fishing grounds and stock structure, particularly the line separating what is now Subarea 4 and Subarea 5 (Halliday and Pinhorn, 1990).

There has been general recognition that a fine scale grid system, which would permit aggregation of fishery information on varying scales, would be more flexible and capable of satisfying the diverse requirements than any fixed grid system. However, continuity is an important practical consideration that has curtailed radical changes in delineation of areas. Location of fishing activity is currently being collected and recorded by Canada and USA on a finer scale than statistical areas. While future consideration could be given to designation of management units that takes advantage of the resolution of the data, it is
impractical at this time to consider management units on a scale finer than statistical areas.

## Distribution and Movements of Cod

There is a fairly long history of studies pertaining to the stock structure of cod on Georges Bank and the vicinity. While these studies include investigations of morphometrics, meristics, parasite prevalence and other characteristics, analyses of tagging results play a prominent role. Loehrke and Cadrin (2007) provide a recent historical review of these studies. A brief summary of some key conclusions from these studies, largely extracted from Loehrke and Cadrin (2007), follows.

- Higgins (1929) tagging: existence of a Nantucket Shoals component with westward and eastward movements in summer, existence of coastal components from Massachusetts Bay to eastern Maine, and there is movement of cod between Georges and Browns Banks.
- Schroeder (1930) tagging and growth: Nantucket Shoals cod do not mix with the coastal components to the northeast. The Nantucket Shoals cod exhibit a pattern of seasonal migration west in the fall to wintering grounds and return in the spring; few cod from the north and east of Cape Cod are found on these wintering grounds.
- Higgins (1931) tagging: Browns Bank cod moved north and east with little movement to the south and west. Most of the cod tagged on Georges Bank stayed on Georges Bank with some movement to Browns Bank and less to Nantucket Shoals.
- Higgins (1933) tagging: Coastal cod stocks appeared to be local with little connection to the offshore banks.
- Wise (1958) tagging: reaffirmed the existence of the Nantucket Shoals component with seasonal winter migration southwest and spring return.
- Wise and Jensen (1960) tagging: eastern Georges Bank cod mix little with westerly and northerly groups but there was evidence of some movement to $4 X$. There was also evidence of another component in the South Channel which migrated inshore to the Nantucket Shoals; cod that wintered along the coast between Rhode Island and New Jersey joined the South Channel cod in the Nantucket Shoals. There were one or more components along the coast of the Gulf of Maine.
- Sherman and Wise (1961) parasite prevalence: separated Gulf of Maine, Georges Bank and Southern New England cod.
- Templeman (1962) synthesis: separated cod into coastal Nova Scotia, coastal Maine, Browns Bank, eastern Georges Bank and South Channel stocks.
- Wise (1963) synthesis: Gulf of Maine consists of many coastal components; Georges and Browns Bank cod are closely related; the South Channel cod are connected to cod in southern New England: the Georges Bank and South Channel cod are divided by the western shoals at about $68^{\circ} \mathrm{W}$.
- Pentilla and Gifford (1976) growth rates (mean length at age): there were similarities between Georges Bank and South Channel/Southern New England cod but these differed from Gulf of Maine.
- Colton et al. (1979) spawning: spawning occurred on Georges Bank, Browns Bank and Nantucket Shoals with different peak spawning times.
- Bowen (1987) synthesis: 5 Y is separate from 4 X and Georges Bank with some north and south movement along the coast. There is evidence of exchange between the Bay of Fundy, Browns Bank and Georges Bank but enough segregation occurs to result in differences in demographic parameters.
- Hunt et al. (1999) tagging: the connection between eastern Georges Bank and Browns Bank is greater than with the South Channel; the strongest connection is between Browns Bank and the Bay of Fundy.
- Ruzzante et al. (1999) genetics: The Bay of Fundy, Browns Bank and Georges Bank are distinct.
- Begg et al. (1999) eggs, larvae and adult distributions, growth, maturity: there is continuity between 5 Y and 5 Z along Cape Cod, and separation between east and west Georges Bank. There are differences between the Gulf of Maine and Georges Bank as well as between east and west Georges Bank.
- Lage et al. (2004) genetics: there is more heterogeneity between Georges Bank and the Nantucket Shoals than between Georges Bank and Browns Bank (see also Wirgin et al 2007).
- O'Brien et al. (2005) synthesis: spawning occurs on eastern Georges Bank, western Georges Bank, Nantucket Shoals, Massachusetts Bay and Ipswich Bay and in distinct zones along the coast of Maine.
- Clark (2005) synthesis: there are structured coastal components with diffuse Bank groups in 4X.

The GARM review (NEFSC 2008) noted that there was a strong interaction between cod in $4 X$ and $5 Z$. Loehrke and Cadrin, in their presentation highlights for the GARM report (NEFSC 2008) urged a re-evaluation of cod stock boundaries, particularly in the vicinity of the Great South Channel. Examination during this review meeting (O'Brien and Worcester 2009) of tag returns from the Northeast Regional Cod Tagging program suggested comparable exchange between eastern Georges Bank and both NAFO Division 4X and western Georges Bank.

Two important commonalities among the results from these historical studies are noteworthy in relation to management units for Georges Bank cod:

- Cod along the coasts of Nova Scotia, New Brunswick and Maine appear to belong to localized coastal stocks with limited connection to offshore banks.
- There appear to be components on Georges Bank (east of about $68^{\circ}$ W), Great South Channel/Nantucket Shoals and Browns Bank with some exchange between Georges and Browns Banks and lesser exchange between Georges Bank and Great South Channel/Nantucket Shoals.

## Summary of Stock Structure and Management Units

The population structure of cod in the broader Gulf of Maine area is characterized as offshore components on Georges Bank, Browns Bank and the Great South Channel/Nantucket Shoals, and localized coastal components that have limited connection to banks. The structure of cod on Georges Bank and the vicinity is complex involving seasonal migration patterns and seasonal mixing grounds with some exchange between putative stocks. Under these circumstances, precise delimitation of stocks is challenging. There are no general guidelines on how closely management unit boundaries should coincide with stock structure before the conservation objectives of the management measures are compromised. These matters typically have to be evaluated on a case by case basis.

It is often considered desirable to devise a management unit to encompass a unit stock. However, practical difficulties in separating catches into their constituent stocks when
fisheries occur on seasonal mixing grounds may lead to management units that encompass stock complexes. There are many examples of this, e.g. Gulf of Maine/Georges Bank herring, cod in 4X and cod in 2J3KL. It may be necessary to introduce supplementary management measures to recognize and protect the components of the stock complex. For Georges Bank, it is possible to separate the catches from eastern Georges Bank. However, questions of the degree of exchange with adjacent areas remain. Arguments can be made to support either $5 Z+$ Subarea 6 or statistical unit areas 5Zjm as management units.

Transboundary resources present additional challenges. Large transboundary management units carry greater bilateral transactional costs due to the greater number of fishermen involved. On the other hand, smaller management units may be ineffective if there is too great an exchange with adjacent areas.

If exchanges with adjacent areas are sufficiently low, treating eastern Georges Bank as the transboundary management unit satisfies the correspondence between stock and management unit and reduces bilateral transactional costs. The evidence suggests that there is a resident spawning population that occupies eastern Georges Bank. However, there are exchanges with cod on Browns Bank and the Great South Channel/Nantucket Shoals. The degree of exchange is not well quantified but is considered to be stronger with Browns Bank. Expanding the transboundary management unit to include either one or both of these adjacent areas introduces complications with respect to the existing agreement for consistent management by Canada and USA. There is no intrinsic reason why assessments of stocks and stock complexes could not be harmonized so that the sum of the parts approximates the total. It is not out of the question therefore for domestic USA management to continue using $5 Z$ and Subarea 6 as a management unit while statistical unit areas 5 Zjm is used as the transboundary management unit. This option, while the least disruptive in relation to the current agreement for consistent management, would benefit from establishment of adequate institutional arrangements to permit evaluation and comparison of the assessments so that their results can be harmonized.

The present agreement for consistent management of cod on Georges Bank between Canada and USA assumes that there is not appreciable net exchange of cod on eastern Georges Bank with adjacent areas. The USA has a requirement for management advice on cod west of eastern Georges Bank. The status quo has been to use an assessment of cod in 5Zjm for transboundary management advice and an assessment of cod in 5Z+6 for USA domestic management advice. While other options could be followed, this option is possibly the least disruptive to the existing processes. However, this approach requires concurrent assessment reviews of 5Zjm and of 5Z+6 to harmonize results.

The remainder of this document deals with the assessment of cod on eastern Georges Bank.

## FISHERY

## Catch

## Canada

Updated Canadian fisheries landings for 1978 to 2007 were extracted from the fisheries statistics database (MARFIS and ZIF) maintained by the Maritimes Region of Fisheries and Oceans Canada (DFO). Comparison with the data used in the 2008 assessment (Clark et al., 2008) revealed that there were no appreciable differences (Table 1, Figure 2). Canadian landings were taken primarily by longliners and otter trawlers during June to December on the northern edge of Georges Bank (Table 2, Figure 3 and 4). Catches in the fourth quarter have become more important in recent years. Dating back to the early 1970s, fishing has been restricted from March through May on spawning grounds. Between 1995 and 2004, fishing by the Canadian groundfish fishery on Georges Bank was not permitted during January and February.

Discards of cod from eastern Georges Bank have been attributed to Canadian groundfish and scallop fisheries. The estimated discards from the Canadian groundfish fisheries for 1997-1999, 2005 and 2006 (Van Eeckhaute and Gavaris, 2004; Gavaris et al., 2006, 2007a), and from scallop fishery for 1978-2007 (Van Eeckhaute et al., 2005; Gavaris, 2007b; Gavaris et al., 2008), were used for this benchmark assessment.

USA
Updated USA fisheries landings for 1978-2007 resulted in minor adjustments to the data used in the 2008 assessment. Almost all USA fisheries landings were taken by otter trawl, primarily during the second quarter (Figure 3).

The collecting and processing of the commercial fishery and landings data has been conducted using two methods during the time series. Prior to 1994, information of the catch quantity, by market category, was derived from reports of landings transactions submitted voluntarily by processors and dealers. More detailed data on fishing effort and location of fishing activity were obtained for a subset of trips from personal interviews of fishing captains conducted by port agents in the major ports of the Northeast. Information acquired from the interview was used to augment the total catch information obtained from the dealer.

In 1994, a mandatory reporting system was initiated requiring anyone fishing for or purchasing regulated groundfish in the Northeast to submit either vessel trip reports (logbooks) or dealer reports, respectively (Power et al. 1997). Information on fishing effort (number of hauls, average haul time) and catch location were now obtained from logbooks submitted to NMFS by vessel captains instead of personal interviews.

Estimates of total catch by species and market category are derived from mandatory dealer reports submitted on a trip basis to NMFS. A multi-tier trip-based allocation has been implemented to combine each mandatory reporting dealer trip with a vessel trip report (VTR) trip or a group of VTR trips of similar characteristics to obtain area fished and effort associated with the dealer trip (Wigley et al. 2007). Since 1994, annual cod landings from eastern Georges Bank have been summarized from all allocated trips fishing in statistical areas 551-552 and 561-562.

Discards of cod from eastern Georges Bank have been attributed to USA otter trawl and scallop fisheries. A ratio of discarded cod to total kept of all species (d:k) was estimated on a trip basis, semi-annually. Total discards (mt) were estimated from the product of d:k and total commercial landings (Wigley et al. 2008). The estimated discards (1989-2007) were used for this benchmark assessment. During 2005-2007, the magnitude of discards was similar to landings and discards were primarily from the otter trawl fisheries.

## Compilation

Combined Canada/USA catches, which averaged 17,508 mt between 1978 and 1992, peaked at $26,463 \mathrm{mt}$ in 1982, declined to $1,684 \mathrm{mt}$ in 1995, fluctuated around $3,000 \mathrm{mt}$ until 2003, and subsequently declined again. Catches in 2007 were $1,796 \mathrm{mt}$, including 472 mt of discards (Table 3, Figure 5). Since 1996, the proportion of the total catch accounted by discards ranged from $2 \%$ to $15 \%$ (Table 3).

## Size and Age Composition

## Canadian Fishery Landings

The size and age composition for the Canadian groundfish fisheries from 1978-2007 were derived for all principal gears and seasons using port and at-sea observer samples. Before 1990, because of the limited number of observer samples and the absence of a recorded landing date, only the port samples were used (Table 4 and Table 5).

For the derivation of size and age composition, a weight-length relationship was used to calculate numbers caught from weight caught. Figure 6 shows the comparison of the quarterly weight-length scatter plot for different years using Canadian at-sea observer samples. The relationships were similar for quarter 1-3 but differed for quarter 4. Because most of the samples since 2001, 502 out of 623, were from scallop discard observer samples, which have fewer large cod, these data were not used to derive weight-length parameters. Therefore, the weight-length parameters derived from 1995-2000 observer samples were applied in the catch at age calculations for all years. With round weight in kilograms and length in centimetres, these values were $a=0.00001045$ and $b=2.983262$ for quarter 1 and quarter 2, $a=0.00001523$ and $b=2.906954$ for quarter $3, a=0.00001205$ and $b=2.977549$ for quarter 4 .

The length samples from the three principal gears, otter trawlers, longliners and gillnetters, were grouped separately by month and then by quarter. Catch at length was obtained by prorating length frequency by the catch from the corresponding fishing gear within each quarter. The gear specific landings and sample numbers are shown in Table 2, 4 and 5. There were insufficient longline samples in the earlier years. A comparison of length frequency was conducted among longline samples from different quarters and otter trawl samples from the same quarter. This indicated that the longline length frequencies peak at a larger size than those of the trawlers' (Figure 7), therefore it was not considered appropriate to borrow samples from the otter trawl for the longline landings. Assuming that the longline length frequencies were similar in different quarters in these years, the longline length samples from other quarters were borrowed when there was no length sample available.

The age composition was estimated by quarter using the age length keys in the corresponding quarter. For the quarters when there were no age samples available in some early years, the age length keys from the USA commercial fishery in 5Zj and 5Zm were applied. The DFO spring survey age length keys were used to supplement first quarter age length keys after 1986. A summary of the number of length and age samples used to estimate Canadian commercial landings catch at age from 1978-2007 is listed in Table 6. The calculated landings at age are shown in Table 7.

## Discards from Canadian Scallop Fisheries

Length frequency samples of cod discards from the scallop fishery are available from the routine at-sea observer trips since August 2004. The age length keys from these samples, supplemented with those from the commercial fishery and DFO survey samples, were used in calculating the discards at age quarterly for this time period.

Observer sampling of discards prior to 2004 was inadequate, therefore survey information was used. A comparison of the 2007 quarterly discards length frequency from the scallop fishery with the DFO and NMFS spring and fall surveys as well as commercial otter trawl samples (Figure 8) indicated that the selectivity from the scallop dredges was similar to the survey trawl. The scallop fishery was more likely to capture smaller cod than the commercial otter trawls. Therefore, for data prior to 2004, the age composition from the averaged DFO and NMFS spring survey for the first half year and from NMFS fall survey for the second half year were used to calculate the scallop discards at age. Then the sum of the first and second halves each year gave the annual scallop discards at age (Table 8).

The lengths and weights at age were assumed to be the same as the research survey samples when no at sea observer sample was available. Before 1986, NMFS spring and fall survey length at age data were used for first and second half year, respectively. After 1986, the averaged value of the DFO and NMFS spring survey data was applied for the first half year. For the weight at age, NMFS spring and fall survey data were only available after 1992 and so a weight-length function derived from the 1992-2000 data was applied to the pre-1992 length data. The number weighted average of length and weight at age of the first and second halves were calculated as the annual values.

## Discards from Canadian Groundfish Fisheries

Cod discards from the Canadian groundfish fisheries were assumed to have the same size and age composition as the otter trawl landings samples. Therefore, the groundfish discards at age were derived by applying the age and length samples from the otter trawl landings to the discard.

## USA Fishery Landings

The age composition of the USA landings was estimated, by market category, from length frequency and age samples pooled by calendar quarter. Landed mean weights were estimated by applying the weight-length equation:

In Weight (kg,live) $=-11.7231+3.0521 \ln$ Length (cm) ,
to the quarterly length frequency samples, by market category. Numbers landed, by quarter, were estimated by dividing the mean weight into the quarterly landings, by market
category, and prorating the total numbers by the corresponding market category sample length frequency. Quarterly age-length keys were then applied to the numbers-at-length to estimate numbers landed at age. Annual estimates of landings at age were obtained by summing values over market category and quarter. Landings were calculated by quarter, rather than by month, since there were months with less than two length frequency samples per market category (i.e., minimum desired for monthly catch estimates).

In some years samples were pooled semi-annually, or annually due to an insufficient number of samples within a quarter. The age composition of the USA landings from eastern Georges Bank was estimated by applying USA length frequencies and combined USA and Canadian age samples for 1978-2006. In 2007, however, Canadian age samples were not applied since there were sufficient USA samples.

Also, in a few years, primarily during the mid-1990s, combined eastern plus western length frequencies were applied due to the lack of sufficient length samples from eastern Georges Bank. The assumption was made that length frequencies from eastern and western Georges Bank would be similar, therefore, all length frequencies were combined to characterize the eastern component of landings. The resulting landings at age from the USA fishery are shown in Table 9.

## Discards from USA Fisheries

Atlantic cod discarded in the eastern Georges Bank area by USA otter trawl and scallop fisheries were estimated using the NEFSC Observer data from 1989-2007. Annual discards at age were estimated by applying combined survey and commercial age-length keys to observer length frequency data (Table 10). No length frequency samples were available for 2001, so estimates of discards were derived based on the average of mean weights at age from 2000 and 2002.

## Compilation

The combined Canada/USA fishery catch at age was obtained by pooling Canadian landings at age and discards at age from the groundfish and scallop fisheries with USA landings at age and discards at age (Table 11, Figure 9). The number of fish captured by the fishery for all ages has declined substantially since 1995. The proportion at age has tended to decrease for ages 2-3 and increase for ages 4-7. Both number and proportion caught at ages 9 and older are lower.

The average of weight at age from Canadian landings, Canadian groundfish and scallop fishery discards, and USA landings and discards, weighted by the respective numbers at age, was used as the Canada/USA fishery average weight at age (Table 12).

## SURVEY INDICES

Surveys on Georges Bank have been conducted by DFO each year (February) since 1986 and by NMFS each autumn (October) since 1963 and each spring (April) since 1968. All surveys use a stratified random design (Figures 10 and 11). In the past assessment, the stratified mean catch in numbers per standard tow was used as the fish population abundance index. To make the meaning of the survey catchability coefficient $q$ clearer, the
stratified mean catch in numbers per tow was changed to total catch in numbers using swept area. The ratio of total numbers to stratified mean numbers per tow was calculated to allow comparability between years. The ratio only differs for years when there was no set in a stratum or when a large area of a stratum was not sampled, both an unusual occurrence.

Survey abundance indices at younger ages have declined substantially for all three surveys since the early 1990s (Tables 13-15, Figures 12-14). In contrast, the abundance indices for ages 4-6 fluctuate without trend since the early 1990s. Abundance indices for ages 9 and older are currently very low.

Population weight at age for beginning of year was derived from the DFO and NMFS spring survey results (1978-1985 DFO weight length relationship applied to NMFS spring average length at age; 1986-1992 DFO weight at age; 1992-2008 sample numbers weighted average of DFO weight at age and NMFS spring weight at age) (Table 16). Figure 15 shows the smoothed weight at age which displays a clearly declining trend since the early 1990s.

Length at maturity from the DFO survey data was analyzed for 2 time periods: 1987-1993 and 1994-2008. Results indicate that both male and female cod appear to be maturing at a smaller size in the recent time period, with length at $50 \%$ maturity decreasing from 42-45 cm to $36-39 \mathrm{~cm}$ for males and from 42 cm to 39 cm for females. No appreciable change was detected in the age at maturity except that 2-year old males showed a slight increase of proportion mature. Length and age at maturity were analyzed from the NMFS spring survey and estimated for the two time periods 1987-1993 and 1994-2008. Both males and females appear to be maturing at smaller sizes in the more recent period with $50 \%$ (median) maturity at length declining from 46 cm to 41 cm for males, and from 44 cm to 40 cm for females. Median maturity at age, however, did not decline: $50 \%$ maturity at age was about 2.3 for males and 2.1 for females for both time periods. At age 3, about $80 \%$ of females were mature in the earlier period and about $90 \%$ were mature in the latter period.

## STOCK STATUS DETERMINATION

The adaptive framework, ADAPT, (Gavaris 1988) was used to calibrate the Virtual Population Analysis (VPA) with the research survey indices. The observed data used in the models were:
$C_{a, t}=$ catch at age for ages $a=1$ to $10+$ and time $t=1978$ to 2007, where $t$ represents the year during which the catch was taken
$I_{1, \mathrm{a}, \mathrm{t}}=$ DFO survey for ages $\mathrm{a}=1$ to 8 and time $t=1986.16,1987.16 \ldots 2007.16,2008.00$
$I_{2, a, t}=$ NMFS spring survey (Yankee 41) for ages $a=1$ to 8 and time $t=1978.29$, 1979.29, 1980.29, 1981.29
$I_{3, a, t}=$ NMFS spring survey (Yankee 36), for ages $a=1$ to 8 and time $t=1982.29$, 1983.29... 2007.29, 2008.00
$I_{4, a, t}=$ NMFS autumn survey, ages $a=1$ to 5 and time $t=1978.69,1979.69 \ldots$ 2007.69.

For comparison with indices, the population numbers at the time of year the surveys occurred were derived by applying the fishing and natural mortality to the numbers at the beginning of the year. Since the fishing mortality rate for 2008 was not known, the DFO survey and the NMFS spring survey were designated as beginning of year for 2008 only. This deviation is not considered to have an appreciable impact as the catch prior to the surveys being conducted is small in recent years.

All model formulations assumed that observation errors for the catch at age data were negligible. Observation errors for the abundance indices at age were assumed to be independent and identically distributed after taking natural logarithms of the values. Zero observations for abundance indices were treated as missing data as the logarithm of zero is not defined. Numbers and fishing mortality for the 10+ age group were derived by aggregating the survivors for ages 9 and 10+ in the previous year.

Estimation was based on minimization of the objective function:
$\sum_{s, a, t}\left(\ln I_{s, a, t}-\left(\hat{\kappa}_{s, a}+\ln N_{a, t}\right)\right)^{2}$, where $s$ indexes survey and $N$ is population abundance.
Statistical properties of estimators were determined using conditional non-parametric bootstrapping of model residuals (Efron and Tibshirani 1993, Rivard and Gavaris 2003). Retrospective analyses were used to detect any patterns to consistently overestimate or underestimate fishing mortality, biomass and recruitment relative to the terminal year estimates.

## Context

## Basic VPA Calibration

For a basic VPA calibration, the annual natural mortality rate, M, was assumed constant and equal to 0.2 for all ages in all years. Fishing mortality on age 9 for 1978 to 2007 was assumed to be equal to the population number weighted average fishing mortality on ages 7 and 8 . The estimated model parameters were:
$v_{a, t}=\ln N_{a, t}=\ln$ population abundance for $a=2$ to 9 at time $t=2008$
$\kappa_{1, a}=\ln$ DFO survey catchability for $a=1$ to 8
$\kappa_{2, a}=\ln$ NMFS spring survey (Yankee 41) catchability for ages $a=1$ to 8
$\kappa_{3, a}=\ln$ NMFS spring survey (Yankee 36) catchability for ages $a=1$ to 8
$\kappa_{4, a}=\ln$ NMFS autumn survey catchability for ages $a=1$ to 5 .
The basic VPA calibration displayed notable age and time residual patterns (Figure 16). However, greatest concern was caused by the persistent retrospective patterns (Figures 18-19) which indicated that contemporary estimates of biomass were consistently lower than previously estimated.

## 2002 Benchmark Formulation

A benchmark assessment review was conducted in 2002 to address concerns about the residual patterns and the retrospective patterns from the assessment. For that consensus model formulation the age 10 catch was used rather than a 10+ age group. The
benchmark formulation was otherwise similar to the basic formulation except that it also estimated population abundance at age 11 for 1999 onwards (referred to as corner). The estimated model parameters for the consensus formulation from that meeting applied to the currently available data were:
$v_{a, t}=\ln N_{a, t}=\ln$ population abundance for $a=2$ to 11 at time $t=2008$ and for $a=11$ at time $t$ $=1999$ to 2007
$\kappa_{1, a}=\ln$ DFO survey catchability for $a=1$ to 8
$\kappa_{2, a}=\ln$ NMFS spring survey (Yankee 41) catchability for ages $a=1$ to 8
$\kappa_{3, a}=\ln$ NMFS spring survey (Yankee 36) catchability for ages $a=1$ to 8
$\kappa_{4, a}=\ln$ NMFS autumn survey catchability for ages $a=1$ to 5 .
Note that the 2002 benchmark formulation excluded DFO survey abundance indices for ages 1 and 8. They are included here for comparative purposes, but do not have much influence on the fit.

The residuals from the 2002 benchmark formulation were somewhat improved compared to the basic formulation, but age and time patterns persisted (Figure 17). The retrospective pattern was greatly improved with contemporary estimates of biomass being either slightly lower or higher than previously estimated (Figures 18-19).

The benchmark formulation resulted in a somewhat domed fishery PR (Figure 20). In view of relatively flat survey catchability at older ages (Figure 21), this feature was not considered a concern at the time. Further, a domed shaped fishery PR was not inconsistent with the decline in catches during the first quarter, when larger cod were more prevalent (Figure 22). The resulting fishing mortality trend from the benchmark formulation also appeared to better reflect the trends in catches (Figure 23).

In recent assessments, the tendency for a dome shaped fishery PR with a more steeply descending limb (Figure 24), dome survey catchability at age (Figure 25) and high estimates of population at older ages (Figure 26) raised concerns. Preliminary exploration of alternative model formulations (Clark et al 2008) suggested that the benchmark formulation may be overestimating population biomass. A benchmark review was therefore recommended by the 2008 TRAC Assessment review (O'Brien and Worcester, 2008).

## Data Features that Models Need to Fit or Explain

The rationale for a dome shaped fishery PR was revisited. While comparisons of length composition from Canadian fisheries between first quarter and second half confirmed that larger/older cod tended to be more prevalent in the first quarter, this was not always the case (Figures 27-30). More importantly, the proportion of the catch attributed to the first quarter only averaged $10 \%$ (Figure 31). As a consequence, the ratio of cod aged 4+ to 7+ was not appreciably affected by the absence of first quarter catches (Figure 32).

Another factor which might contribute to a dome shaped fishery PR is closed area II (Figure 10), which has been not accessible for the USA fishing fleets since 1994. The DFO spring survey data from 1987-2007 were used to examine fish size composition changes before and after the area closed. The survey catch data from strata $5 Z 3$ and $5 Z 4$ in 5Zjm were separated into two parts, east of 67.333 W and north of 41.0 N , and this area
combined was considered to be an approximation of closed area II (Figure 10). Figure 33 and 34 are the age structure comparisons of inside and outside closed area II. There is no consistent pattern of difference both for pre- and post- 1994. Table 17 shows the comparison inside and outside closed area II for the 4+ age group proportion and weighted average age. Based on this information, no clear conclusion could be made about the impact of closed area II on the size distribution of fish.

Despite reduced catches of ages 4-6 since the mid-1990s, the catch of older fish has not increased appreciably (Figure 35).

Smoothed survey trends indicate a progressive decline for ages 2-3, a decline at ages 4-6 during the early 1990s followed by a moderate increase, and fluctuation without much trend at ages 7-8 (Figure 36). The 2002 benchmark formulation does a better job of fitting the ages 4-6 trend, but generates more fish at ages 7-8 than indicated by the surveys.

Time trends in survey catchability at age, extracted from the basic formulation, indicate that survey catchability has increased since the mid 1990s for ages 4-6 and perhaps age 3, but not necessarily for other ages (Figure 37). Indeed, the catchability appears to decline at ages 1 and 2.

Total mortality calculations suggest that there may have been a decline around the mid 1990s, but total mortality is currently as high or higher compared to pre-1995 (Figure 38). Notably, total mortality is appreciably higher for ages 6-8 compared to ages 4-5. Relative exploitation (fishery catch / survey catch), in contrast, suggests that fishing mortality decreased substantially in the mid 1990s (Figure 39).

Estimates of instantaneous total mortality $(Z)$ were derived from both DFO and NMFS spring survey total catch indices and from fishery catch at age data. $Z_{45}$ and $Z_{678}$ were referred to as the approximation to total mortality of ages $4-5$ and ages 6-8 in year i , respectively.

$$
\begin{aligned}
& Z_{45}=\ln \left(\left(\sum \text { age } 4+\text { age } 5 \text { for years } i\right) /(\Sigma \text { age } 5+\text { age } 6 \text { for years } i+1)\right) \\
& Z_{678}=\ln ((\Sigma \text { age } 6+\text { age } 7+\text { age8 for years } i) /(\Sigma \text { age } 7+\text { age8+age9 for years } i+1))
\end{aligned}
$$

The LOESS smoothing method was fit to each of the total mortality time series data (Cleveland, 1979).

In summary, the following observations can be made:

- there is no support for a change to a steeply domed fishery PR,
- there are indications of increased survey catchability for ages 3 or 4-6 in recent years,
- total mortality declined somewhat in the mid 1990s but remains high,
- there are indications of higher $M$ for fish 6 years old and older, and
- the relative exploitation rate has declined in recent years.

## Model Options

## No Split/Increase M

Both DFO and NMFS spring surveys show an increase in the number of fish of age 4-6 in recent years, but no increase for the older fish (Figure 12 and 13), despite a substantial decrease in the catch for ages $4-6$ since 1994 (Figure 35). Further, the calculated total
mortality rate, Z, from survey and catch data remains high after 1994 (Figure 38). This suggests that natural mortality might have increased in recent years. The starting year for an increase in natural mortality was selected as 1994, the date when new management measures were introduced and stock abundance was low.

ADAPT setup for this model:

- M=0.2 for ages 1-10+, years 1978-1993.
- $\mathrm{M}=0.2$ for ages 1 to age $\mathrm{A}-1$, from 1994-2007, then estimated as one block for ages $A$ 10+.
- In 2008, N is estimated for ages 2-9.
- $F$ for age 9 is calculated as the weighted average of $F$ on age 7 and 8 , for years 1978 2007.

In order to decide on a suitable age A at which the higher M begins, a few trial VPAs were done starting at different ages from 4 to 7 , respectively. The time and age patterns in F , age patterns in survey catchability $q$, sum of square residuals (SSQ) and Akaike's Information Crieteria (AIC) were used to diagnose the fits (Figures 40-42). The model with the $M$ change starting at age 6 has the lowest SSQ, with a flat topped fishery PR and survey catchability, and estimates M as 0.7 . The AIC comparison shows that the model starting at age 6 has the highest Akaike weight (0.95) of the four models (Table 18). Estimation of $M$ can be erratic due to the correlation of survey $q$ and $M$. Therefore comparisons were made with M fixed at different values from 0.2 to 0.7 starting at age 6 (Figures 43-45). The F for post-1994 remained as high as the F during the 1980s when $M=0.2,0.3$ and 0.4 . The trial with $M=0.7$ has flat shaped survey catchablity $q$, the lowest SSQ with an Akaike weight of 0.83 (Table 19). The retrospective runs are used to confirm the consistency of $M$ estimation with time changes (Figure 46). The estimated $M$ was around 0.7 for all the terminal years from 2000-2008. Based on the above analysis, the model with fixed $M$ at 0.7 starting at age 6 from 1994 (referred to as "no split M 0.7 ") was examined further.

Tables 20-21 show the assessment result using "no split M 0.7" model formulation. This model produces a $3+$ biomass of about $17,500 \mathrm{mt}$ in 2008. The averaged fishing mortalities ( $F$ ) in the 3 time blocks (1978-1993,1994-2000,2001-2007) are around 0.5, 0.25 and 0.18 , all with flat shaped fishery PR patterns (Figure 47). The survey catchability $q$ of the DFO spring survey is 0.8 at fully recruited age 5 (Figure 48). Comparisons between the estimated $q$ and the $q$ calculated as the ratio of the survey abundance index to estimated population numbers shows a clear increasing trend of calculated $q$ for ages 4 to 6 , which occurred around the mid 1990s (Figure 49) . For ages 4 and 5, most of the calculated $q$ points are below the estimated $q$ for the early years and above that for the recent years. This suggests that the survey catchability $q$ has changed.

## Split/Constant M

At the GARM III meeting, the $q$ changed model was accepted as the assessment model of $5 Z+6$ cod (NEFSC 2008). In that model, the survey abundance indices were split at 19931994, and constant $\mathrm{M}=0.2$ assumed for all the years. This model was also explored the 2009 benchmark meeting for Atlantic cod on eastern Georges Bank. It is referred to as the "split M 0.2" model.

The estimated beginning year population abundance and annual fishing mortality are presented in Tables 22-23. The model produces almost the same level of fishing mortality
at 0.6 for the 3 time blocks, despite the restrictive management measures that have been in place in the recent time period (Figure 50). The 3+ biomass in 2008 is estimated at around $9,000 \mathrm{mt}$. Survey catchability $q$ of the DFO spring survey reaches 3.0 at fully recruited age 6, which seems incredibly high and represents a marked change from pre1994 (Figure 51). There is a clear increasing trend in both model estimated and calculated $q$ for ages 3 to 8; however, in a few ages, most of the calculated $q$ points are still below the estimated q, greatly affected by the survey year effects from high catches (Figure 52). Our ability to estimate $q$ well may be compromised by the short time series for data since 1994 and the high variability in survey catches, both confounded with potential changes in M

## Split/ M Change

Due to the problems with the above 2 models, a model with both $q$ and $M$ changes was explored. This model has the same setup as the "split M 0.2 " model, except that M was estimated for ages A-10+ for the years 1994-2007.

The results for the trial VPA where M was estimated for various starting ages from 4-8 are presented in Figures 53-55. The fishery PR and survey catchablity increased with ages when the starting age was 4 or 5 , but became dome shaped when the starting age was 7 or 8. From the fit statistics, a starting age of 6 for an increase in $M$ had the smallest SSQ value and the Akaike weight was relatively low at $28 \%$ (Table 24). A starting age of 5 or 7 had $21 \%$ of the selection probability, which means that there was some uncertainty about the best starting age. The high variability in survey data and the correlation of survey $q$ and estimated M are suspected to contribute to the difficulty in clearly identifying a preferred starting age. A few VPA trials were done fixing M at different values from 0.2 to 0.7 with a starting age of 6 (Figure $56-58$ ). For runs with $M=0.2,0.3$ and 0.4 , the estimated F in 1994-2000 remained as high as the $F$ during the 1980 s. An $M=0.5$ had the smallest SSQ value, and flat survey $q$ at older ages. AIC also selected the $M=0.5$ model with an Akaike weight of 0.35 , while $\mathrm{M}=0.6$ had the weight of 0.31 and $\mathrm{M}=0.4$ had the weight of 0.18 (Table 25). M between 0.4-0.6 accounted for about $80 \%$ of the probability in the fit statistics. The retrospective runs had the same estimated $M$ values for all the terminal years except for 2003 and 2004 which had lower M values with higher CVs (Figure 59). Therefore, a model with M fixed at 0.5 and with a starting age of 6 , referred to as "split M $0.5^{\prime \prime}$ model, was examined further.

This "split M 0.5" model estimated Ages 3+ biomass at about 11,500 mt in 2007 (Table 26). Estimates of average fishing mortality were 0.6 from 1978 to 1993, 0.45 from 1995 to 2000 and 0.35 from 2001 to 2007 (Table 27, Figure 60). Survey catchability $q$ for the DFO spring survey was 1.5 at fully recruited age 5 (Figure 61). The estimated $q$ of younger fish at ages 1 and 2 decreased for the recent time period, slightly increased for age 3, and a clear increasing trend was seen for older fish (Figure 62). Year effects from high catches persisted. For a few ages, most of the calculated $q$ points were still below the estimated $q$.

## Comparisons

The following diagnostics were used to compare the above three models.

- Survey catchability $q$ (Figures 48, 51 and 61)
- Population abundance (Figure 63)
- Estimated biomass trend compared with survey biomass trend (Figure 64)
- Population biomass (Figure 65)
- Age patterns in F (Figures 47, 50 and 60)
- Time patterns in F with respect to catch (Figure 66)
- Residual patterns (Figure 67)
- Retrospective pattern (Figure 68-69)
- AIC and Bayesian Information Criteria (BIC, which penalizes models with more parameters) selection (Table 28)

All three models can be supported or criticized. Model fit diagnostics hardly provide convincing selection results among them. There was no strong biological information or knowledge to support large changes of survey $q$ or M. Some evidence indicated that both survey $q$ (time trends of survey catchability $q$ ) and M (both AIC and BIC selected the model with high M ) have changed. The "split M 0.5 " model displays the following desirable features:

- Flatter survey catchablility at older ages
- Calculated time trends of $q$ from VPA support $q$ changes, and smaller changes in survey catchability at all ages after 1994
- Flatter fishery PR
- Time trends of $F$ are more consistent with catch in the past
- Better retrospective patterns of 3+ biomass
- The $Z$ from survey and catch support a high $Z$ of older fish
- Fit statistics favour "split M 0.5 " model over the other 2 models

However, there are strong residual patterns no matter which model is used (Fig 67). A residual autocorrelation analysis was conducted by calculating the lag 1 autocorrelation coefficient using the Yule-Walker function and a comparison was made between the "split M 0.2 " model and "basic VPA calibration" model. There was no significant difference in the autocorrelations between these two "split" and "no split" models (Figure 70). Most of the residual patterns were associated with year effects in the survey data. A sensitivity analysis was done by dropping some years of survey data (Table 29) from the calibration indices based on low or high survey coefficients of variation (CV). The "split M change" model was used to compare these results. There was no significant difference for 3+ biomass and 2008 fish population numbers (Figure 71). Furthermore, the selection criterion for dropping survey years was quite arbitrary, and no standard method has been documented. Because of the noisy survey abundance indices, and the high correlation of $q$ and $M$, there are uncertainties about the scale and time of $M$ and $q$ changes.

## Other model explorations

## Fratio in VPA

A further exploration was done using the Fratio method in VPA. In this method, the F on age 10+ group was calculated as a ratio of $F$ on age 9 . M was set up as 0.2 for all the ages and years. In 2008, N was estimated for ages 2-10+. This model formulation resulted in a dome shaped fishery PR and survey catchablility $q$ (Figure 72), which was similar to the 2002 benchmark formulation. It was suspected that the amount of older fish was overestimated (Figure 73).

## q power in VPA

Under the assumption that survey catchablility depends on population abundance, a VPA model formulation in which a power function was used for the relationship between survey and population abundance was explored. This method had a similar pattern in population
abundance and fishery PR to the basic formulation (Figure 74). A strong retrospective pattern was expected from this model formulation.

## ASAP

The Age Structured Assessment Program (ASAP) forward projection model was run as an exploratory alternative model to the VPA. The ability of this model to include additional catch and survey indices when no age composition data is available can provide additional information on stock productivity. ASAP model runs were conducted for both Eastern Georges Bank (EGB, 5Zjm) and Georges Bank (GB, 5Z + subarea 6) cod. There was no term of reference to present assessment results for GB cod at this benchmark meeting; however, applying the same model formulations to both management units provided a useful comparison.

Three model formulations were run for both EGB and GB cod. The base formulation allowed the PR to be freely estimated, the 'flat PR' formulation imposed a flat topped PR pattern, and the 'dome PR' formulation imposed a dome shaped PR pattern. The PR for each fleet was estimated by age, with two selectivity blocks within each fleet based on changes in management measures (quotas, mesh regulations, area closures) during those years. The selectivity blocks were between 1998 and 1999 for the US western GB fleet, between 1994 and 1995 for US eastern GB fleet, and between 1992 and 1993 for the Canadian eastern GB fleet.

The input data for all three models were the same, with only the PR formulation varying. For the GB cod, the GB cod landings were disaggregated into 3 fleets: US western GB, US eastern GB, and Canadian EGB. For the EGB, the EGB cod landings were disaggregated into two fleets: US EGB and Canadian EGB. The times series of landings (1978-2007) and survey abundance indices as area-swept estimates (NEFSC spring 36 and 41 Yankee ages 1-8, DFO ages 1-8, and NEFSC autumn ages 1-5 for GB and ages 1-5 for EGB) were same as those used in the assessment VPA. Landings and survey biomass estimates from 1964-1977, without age composition data, were also input to the model. The survey time series was not split.

ASAP diagnostics provided similar partial recruitment and retrospective patterns to those of the VPA. However, the model provides the capability for data input of disaggregated catch at age by fleet and historical catch without age composition. These options allow for more flexibility for weighting of input data and in examining partial recruitment by fleet.

## EGB Model Results

The base and 'dome PR' formulations had a similar pattern in the survey catchability $(q)$ at age. The NEFSC 36 (Yankee trawl) and the DFO surveys exhibited a domed PR at age 5, whereas the NEFSC 41 (Yankee trawl) exhibited relatively flat-topped PR patterns. The 'flat PR' formulation exhibited flat-topped $q$ after age 6 for NEFSC 41 and DFO, and after age 3 for NEFSC autumn, and the NEFSC 36 tended toward a dome PR after age 5.

The fishery selectivity of the base run was generally flat topped for the early selectivity block, but exhibited a strong dome for the latter selectivity block. Trends in F and SSB (Figure 75) estimates were similar for all three runs, with the 'dome' run estimating the lowest Fs and the 'flat' runs the highest. The opposite was observed in SSB, with the 'dome' run indicating the highest SSB and the 'flat' runs the lowest. All three runs exhibited
a retrospective pattern in $F$ (Figure 76), SSB (Figure 77) and age 1 recruits (Figure 78); however, the lowest magnitude occurred in the 'dome' run.

A sensitivity analysis was also conducted to examine the effect of an increase in the variability of the survey indices from a coefficient of variability (CV) of 0.4 to 0.8 . The higher CV resulted in higher F, lower SSB and an increase in the retrospective pattern relative to the $\mathrm{CV}=0.4$ run. The higher variability in the survey allowed the catch at age to have more influence in the estimation.

## GB Results

The base formulation showed a relatively flat catchability by age 6 for all 4 surveys with some slight decline by age 8 . The 'flat PR' formulation showed increasing $q$ with age for the NEFSC 36 and DFO survey, and relatively flat $q$ at age after age 4 for NEFSC 41 and NEFSC autumn. The 'dome PR' showed a strong decline in $q$ after age 6 for the DFO survey, and less of a dome at age 6 for NEFSC 36 for the other 3 surveys. The base run fishery selectivity was generally flat topped for both the US western and Canadian fleets, but tended to a dome for both selectivity blocks for the US eastern fleet. Trends in F and SSB estimates (Figure 79) were similar for all three runs, with the 'dome' run estimating the lowest Fs and the 'flat' runs the highest. The opposite was observed in SSB, with the 'dome' run indicating the highest SSB and the 'flat' runs the lowest. All three runs exhibited a retrospective pattern in F (Figure 80), SSB (Figure 81) and age 1 recruits (Figure 82); however, the lowest magnitude occurred in the 'dome' run.

## Model Consensus

"Split M 0.5" model is indicated by fit diagnostics as the basis for management advice. However, it is recommended during the benchmark review meeting that the results from the comparable model "split M 0.2 " model also be considered. Until the fate of the 2003 year class has been documented (ages 6+) it will be necessary to use these two models to adequately account for uncertainty in the assessment. Doing so acknowledges that there is considerable uncertainty about selection of a single appropriate model. It is also notable that domestic USA management of NAFO Divisions $5 Z+6$ is based on a model with split survey time series and natural mortality of 0.2 (O'Brien and Worcester, 2009).

## REFERENCE POINTS

The Transboundary Management Guidance Committee has adopted a strategy to maintain a low to neutral risk of exceeding the fishing mortality limit reference, $\mathrm{F}_{\text {ref }}=0.18$. Changes in $M$ and changes in weight at age would invoke an update of $F_{\text {ref. }}$. Results from dynamic pool models would indicate a higher $\mathrm{F}_{\text {ref. }}$. However, incorporating a Beverton-Holt stock recruitment relationship into the dynamic pool models would cause a reduction in $\mathrm{F}_{\text {ref }}$ (Figure 83). Inability to characterize a stock-recruitment relationship and uncertainty about the magnitude and persistence of any change in $M$ suggest that it may be imprudent to increase the $F_{\text {ref }}$ on the basis of results from dynamic-pool models (Figure 84). There do not appear to be any time trends in recruits per spawner that might be associated with compensatory processes in response to either higher M or reduced biomass (Figure 85). Further, there are indications that weight at age has increased in recent years, particularly at younger ages (Figure 15, includes preliminary weight at age from 2009 survey). It may be premature to adjust $F_{\text {ref }}$ for changes in growth that may not be persistent.

## PROCEDURE FOR PROJECTION

The outlook is provided in terms of consequences with respect to the harvest reference points for alternative catch quotas in 2009. Uncertainty about standing stock generates uncertainty in forecast results, which is expressed here as the risk of exceeding $\mathrm{F}_{\text {ref }}=0.18$ or the risk that biomass will not increase by a given percentage. The risk calculations assist in evaluating the consequences of alternative catch quotas by providing a general measure of the uncertainties. However, they are dependent on the data and model assumptions and do not include uncertainty due to variations in weight at age, partial recruitment to the fishery, natural mortality, systematic errors in data reporting or the possibility that the model may not reflect stock dynamics closely enough.

For projections, the 2005-2007 average values for the fishery weight at age and the 20032007 average values for partial recruitment pattern were assumed for 2008-2009 and the 2006-2008 average values were assumed for beginning of year population weight at age in 2009-2010. In general, 5 year averages were used when trends are not apparent and shorter time periods were used to account for appreciable trends.

## Projection and Risk Analyses

Illustrative projections were conducted to evaluate how differences in stock status determination using the various models translated into differences for catch advice and biomass trajectory. The "no split M 0.7 " model generated a fairly high catch at $\mathrm{F}=0.18$ but resulted in an almost certain biomass decline (Table 30, Figure 86). In contrast, the "split M 0.2 " model generated a relatively low catch at $\mathrm{F}=0.18$ but provided the greatest prospects for biomass increase. The results from the "split M 0.5 " model were intermediate.

## SUMMARY

The TRAC consensus was to accept two models to determine stock status for the annual assessment. These were the "split M 0.2 " and "split M 0.5 " models. The F reference point was not updated, however, given uncertainties in growth, $M$, and the stock-recruit relationship.
