## Canadä'

#### Abstract

The combined Canada/US yellowtail flounder (Limanda ferruginea) catch increased from 2008 $(1,275 \mathrm{mt})$ to $2009(1,778 \mathrm{mt})$ due mainly to an increase in quota. The 2005 year class did not appear strong in any of the recent surveys and did not dominate the catch, causing the assessment model to estimate the 2005 year class as only average. The 2005 year class had been estimated as one of the largest since the mid 1970s in the previous assessment. This change in perception of the 2005 year class caused the estimated spawning stock biomass to be lower than estimated in the last assessment. The recent trend in estimated spawning stock biomass is increasing, with 2009 estimates around $14,000 \mathrm{mt}$, but still well below the US rebuilding target of $43,200 \mathrm{mt}$. The 2005 and 2006 year classes were estimated to be about average at 23.9 million and 22.2 million, respectively, the 2007 year class is well below average, and the 2008 year class is estimated to be the lowest in the time series at 6.1 million. Fishing mortality rates for fully recruited ages $4+$ were estimated to be 0.15 in both 2008 and 2009, below the $\mathrm{F}_{\text {ref }}$ of 0.25 . Assuming a 2010 catch equal to the $1,956 \mathrm{mt}$ quota, a combined Canada/US yield of about $3,400 \mathrm{mt}$ in 2011 results from the deterministic application of $\mathrm{F}_{\text {ref }}=0.25$. The current US rebuilding strategy cannot be achieved even with a fishing mortality rate of zero. Examination of a range of alternative rebuilding strategies resulted in median catches in 2011 ranging from 600 mt to $2,700 \mathrm{mt}$.

These results are based on a single model formulation, denoted Split Series, as opposed to the previous assessment which provided the results from two model formulations. The previous assessment treated the unusual large tows for the 2008 and 2009 DFO survey as either the same values in the assessment (i.e. "Including") or removed from tuning (i.e. "Excluding"), as a way to bracket the uncertainty associated with these surveys. This assessment down-weights the DFO 2008 and 2009 surveys, as recommended by the TRAC last year to produce results approximately half way between the two previous formulations.

Despite splitting the survey time series to eliminate the retrospective pattern, this assessment now shows a moderate retrospective pattern in SSB due to the change in perception of the 2005 year class. Alternative projections which adjust the starting population abundance to account for the retrospective pattern lead to lower catch advice than the standard projections. For example, fishing at $\mathrm{F}_{\text {ref }}=0.25$ has a median 2011 catch of approximately $2,100-2,300 \mathrm{mt}$ depending on the method used to adjust for the retrospective pattern. Additionally, projections which utilize only recent recruitment levels have lower rebuilding probabilities and lower expected catch in medium term projections, although the 2011 catch advice is essentially unaffected.

## RÉSUMÉ

Les captures combinées de limande à queue jaune (Limanda ferruginea) du Canada et des États Unis ont augmenté de $2008(1275 \mathrm{tm})$ à 2009 ( 1778 tm ), cela en raison surtout d'une hausse du quota. La classe d'âge de 2005 n'a pas semblée forte dans les relevés récents et elle n'était pas dominante dans les captures; de ce fait, elle est jugée seulement moyenne dans le modèle d'évaluation, alors qu'elle avait été considérée comme une des plus fortes classes d'âge depuis le milieu des années 1970 dans l'évaluation précédente. En raison de ce changement dans l'appréciation de la classe d'âge de 2005, l'estimation de la biomasse du stock de reproducteurs est inférieure à celle de l'évaluation précédente. La tendance récente de la biomasse estimée du stock de reproducteurs est en hausse, l'estimation pour 2009 se situant alentour de 14000 tm , mais restant encore bien inférieure à l'objectif de rétablissement fixé par les États-Unis, qui est de 43200 tm . On a estimé que les classes d'âge de 2005 et de 2006 se situaient à peu près dans la moyenne, avec un effectif de 23,9 millions et de 22,2 millions, respectivement; la classe d'âge de 2007 est, quant à elle, bien inférieure à la moyenne, tandis que celle de 2008 est considérée comme étant la plus basse de la série chronologique, avec un effectif de 6,1 millions. Le taux de mortalité par pêche parmi les limandes à queue jaune pleinement recrutées des âges $4+$ a été estimé à 0,15 en 2008 et également en 2009, ce qui est inférieur à Fréf. ( 0,25 ). Dans l'hypothèse où les captures de 2010 seraient égales au quota de 1956 tm , l'application déterministe de $\mathrm{F}_{\text {réf. }}=0,25$ aboutirait à un rendement combiné de la pêche canadienne et américaine d'environ 3 400 tm en 2011. L'actuelle stratégie de rétablissement adoptée par les États-Unis est inatteignable, même avec un taux de mortalité par pêche de zéro. D'autres stratégies de rétablissement ont été examinées; elles se traduiraient par des captures médianes allant de 600 tm à 2700 tm en 2011 .

Comparativement à l'évaluation précédente, qui comprenait deux formules de modèle, les résultats présentés ici sont fondés sur une seule formule de modèle, dite de la «série fractionnée ». Dans l'évaluation précédente, on avait traité les gros traits inhabituels des relevés du MPO de 2008 et de 2009 de deux façons, soit en les intégrant à l'évaluation en leu donnant la même pondération que ceux des autres relevés (option d'inclusion) soit en les écartant de l'ajustement du modèle (option d'exclusion), pour refléter l'incertitude associée à ces relevés. Dans la présente évaluation, on attribue une moindre pondération aux relevés du MPO de 2008 et 2009, ainsi que l'a recommandé l'an dernier le CERT, pour obtenir des résultats se situant à mi-chemin environ de ceux des deux formules précédentes.

Malgré le fractionnement opéré dans la série chronologique des relevés pour éliminer la tendance rétrospective, la présente évaluation reflète maintenant une tendance rétrospective modérée dans la BSR, due au changement dans l'appréciation de l'effectif de la classe d'âge de 2005. D'autres projections dans lesquelles la valeur de départ de l'abondance de la population est corrigée en fonction de la tendance rétrospective aboutissent à des captures recommandées inférieures à celles des projections standards. Ainsi, pour une pêche à $\mathrm{F}_{\text {reff. }}=0,25$, les captures médianes se situent à 2100 tm 2300 tm environ, selon la méthode qui a été utilisée pour tenir compte de la tendance rétrospective. De plus, les projections fondées uniquement sur le recrutement récent aboutissent à de plus faibles probabilités de rétablissement et à de moindres captures à moyen terme, quoique pour l'essentiel cela n'ait pas d'effet sur la recommandation concernant les captures de 2011.

## INTRODUCTION

The Georges Bank yellowtail flounder (Limanda ferruginea) stock is a transboundary resource in US and Canadian jurisdictions. This paper updates the last stock assessment of yellowtail flounder on Georges Bank, completed by the US and Canada (Legault et al. 2009) addressing technical recommendations from the 2005 benchmark review (TRAC 2005). A primary objective of the benchmark review was to address the retrospective pattern that had been apparent from assessments conducted during the previous several years. During the benchmark assessment meeting, several analytical models were reviewed, all of which indicated poor correspondence between the catch at age and survey abundance at age that could not be reconciled. Various possible reasons for the retrospective pattern were identified including an increase in natural mortality, large amounts of unreported catch, and changes in survey catchability since 1995. The consensus view from the benchmark meeting was that management advice should be formulated on the basis of results from several approaches:

- Analysis of data from survey and fishery (trends in relative fishing mortality, F, and total mortality, Z)
- 'Base Case’ VPA model formulation from 2004 assessment
- Two new VPA model formulations with minor \& major changes to Base Case.

The analytical methods used in the current assessment were based on revised model formulations adopted during the 2005 TRAC benchmark review using updated information from both countries on catches and survey indices of abundance. During the 2009 TRAC meeting, it was decided that neither the 'Base Case' or 'Minor Change' VPA formulation would be considered any longer because neither had been used for management advice in a number of years (O'Brien and Worcester 2009). The 'Major Change' VPA formulation was modified from the benchmark and the modified formulation will be referred to as the 'Split Series' model in this document, since it is now the default model.

Last year, two 'Major Change' VPA formulations were used to provide catch advice: "Including" used the full time series of all surveys while "Excluding" did not include the Canadian 2008 or 2009 survey information due to the influence of single large tows. Both formulations indicated that fishing mortality in 2008 was below the target rate $\mathrm{F}_{\text {ref }}=0.25$ and that biomass was increasing rapidly due to a strong 2005 year class. Projections indicated that catching the TAC of $2,100 \mathrm{mt}$ in 2009 would result in a fishing mortality rate below $\mathrm{F}_{\text {ref }}$ ( $\mathrm{F}_{2009}=0.09$ Including, 0.12 Excluding). US rebuilding projections were also conducted which required F in years 2010 through 2014 to be 0.085 (Including) or 0.02 (Excluding). Due to an inability to agree on a consensus catch quota, the two countries each set their quota independently. The US set a 2010 fishing year (May 1 - April 30) quota of 1,200 mt and Canada set a 2010 calendar year quota of 756 mt , for a total combined US/Canada catch of $1,956 \mathrm{mt}$.

Yellowtail flounder range from southern Labrador to Chesapeake Bay and are typically caught at depths between 30 and 70 m . Recently, fishermen have reported catching yellowtail flounder in deeper waters than they are traditionally found. An examination of catch by depth did not support a statistically significant change in the distribution of yellowtail flounder at depth over time (see TRAC Working Paper 17 Hyun et al. 2010). A major concentration occurs on Georges Bank from the northeast peak to the Great South Channel. Yellowtail flounder have previously been described as relatively sedentary, although a growing body of evidence counters this
classification with off bottom movements (Walsh and Morgan 2004; Cadrin and Westwood 2004), limited seasonal movements (Royce et al. 1959; Lux 1963; Stone and Nelson 2003), and transboundary movements both east and west across the Hague Line (Stone and Nelson 2003; Cadrin 2005). On Georges Bank, spawning occurs during late spring and summer, peaking in May. Eggs are deposited on or near the bottom and after fertilization float to the surface where they drift during development. Larvae are pelagic for a month or more, then become demersal and settle to benthic habitats. Based on the distribution of both ichthyoplankton and mature adults, spawning occurs on both sides of the Hague Line. Growth is sexually dimorphic, with females growing at a faster rate than males (Lux and Nichy 1969; Moseley 1986; Cadrin 2003). Yellowtail flounder mature earlier than most flatfish with approximately $50 \%$ of age two females mature and nearly all age 3 females mature.

## MANAGEMENT

Historical and new information pertaining to the current management unit for the Georges Bank yellowtail flounder stock was reviewed during the 2005 benchmark assessment. Tagging data, larval distribution, vital population parameters (i.e. growth, survival, recruitment, reproduction, abundance), and geographic patterns of landings and survey data indicate that Georges Bank yellowtail flounder comprise a relatively discrete stock, separate from those on the western Scotian Shelf, off Cape Cod and southern New England (Royce et al. 1959; Lux 1963; Neilson et al. 1986; Begg et al. 1999; Cadrin 2003; Stone and Nelson 2003). Based on information from a comprehensive review by Cadrin (2003) and recent results from cooperative science/industry tagging programs conducted by the US and Canada, there does not appear to be any justification for redefining the geographic boundaries of the Georges Bank yellowtail flounder stock management unit.

The management unit currently recognized by the US and Canada for the transboundary Georges Bank stock includes the entire bank east of the Great South Channel to the Northeast Peak, encompassing U.S. statistical reporting areas 522, 525, 551, 552, 561 and 562 (Fig. 1a) and Canadian fisheries statistical areas $5 \mathrm{Zj}, 5 \mathrm{Zm}, 5 \mathrm{Zn}$ and 5 Zh (Fig. 1b). Both the US and Canada employ the same management unit.

In 1985, the World Court determined US and Canadian jurisdictions for Georges Bank fishery resources. At that time, there was no Canadian fishery for yellowtail. When a Canadian fishery developed in the early 1990s, US and Canada were exchanging information but doing separate assessments. In the late 1990s, joint assessments were developed, and in 2001 a sharing agreement was formed (TMGC 2002). Since the establishment of the US and Canada sharing agreement in 2001, advice for the Georges Bank yellowtail flounder relied primarily on a bilateral management system provided by the Transboundary Management Guidance Committee (TMGC). The agreement includes total allowable catch for each country based on a formulaic calculation using both historical catch and current spatial stock distribution. The quota sharing agreement between the two countries requires that catches from all sources be counted against the national allocations, regardless of whether the catch was landed or discarded. Although there is coordination between the US and Canadian fishery management, objectives between the two countries remain inconsistent, with US law requiring stock biomass rebuilding targets that are not part of Canadian management.

## THE FISHERIES

Exploitation of the Georges Bank stock began in the mid-1930s by the US trawler fleet. Catch (including discards) increased from 400 mt in 1935 to $9,800 \mathrm{mt}$ in 1949, then decreased in the early 1950s to $2,200 \mathrm{mt}$ in 1956, and increased again in the late 1950s (Fig. 2). The highest annual catches occurred during 1963-1976 (average: $17,500 \mathrm{mt}$ ) and included modest catches by distant water fleets (see Other Landings, Table 1). No catches of yellowtail by nations other than US and Canada have occurred since 1975. Catches averaged around 3,500 mt between 1985 and 1994, then dropped to $1,135 \mathrm{mt}$ in 1995 when fishing effort was markedly reduced in order to allow the stock to rebuild. The US fishery in the management area has been constrained by spatial expansion of Closed Area II in 1994 (Fig. 1a) and by extension to year-round closure in December 1994, as well as mesh size and gear regulations and limits on days fished. In 2004, a Yellowtail Special Access Program (SAP) in Closed Area II allowed the US bottom trawl fishery short-term access to the area for the first time since 1995. This SAP did not continue in subsequent years. A directed Canadian fishery began on eastern Georges Bank in 1993. Catches by both nations (including discards) steadily increased (with increasing quotas) from a record low of $1,135 \mathrm{mt}$ in 1995, when the stock was considered to be in a collapsed state, to $7,419 \mathrm{mt}$ in 2001. Since 2004, decreasing quotas and an inability of Canadian fishermen to fill their portion of the quota have resulted in declining catches through $2008(1,275 \mathrm{mt})$ with an increase in 2009 to $1,778 \mathrm{mt}$.

## United States

The principle fishing gear used in the US fishery to catch yellowtail flounder is the otter trawl, accounting for more than $98 \%$ of the total USA landings in recent years, although sea scallop dredges have accounted for some historical landings. US trawlers that land yellowtail flounder generally target multiple species on the southwest part of the Bank, and on the northern edge along the western and southern boundaries of Closed Area II. Current levels of recreational fishing are negligible.

Landings of yellowtail flounder from Georges Bank by the US fishery during 1994-2009 were derived from the new trip-based allocation described in the GARM III Data meeting (GARM 2007, Palmer 2008, Wigley et al. 2007a). Changes to the data in recent years caused a change in the landings value for 2007 from $1,061 \mathrm{mt}$ to $1,072 \mathrm{mt}$. This change was incorporated in the catch at age data used in the assessment. US landings have been limited by quotas in recent years. Total US yellowtail landings (excluding discards) for the 2009 fishery were 975 mt , an increase of $30 \%$ from 2008 (Table 1; Fig. 2).

US discarded catch for years 1994-2009 was estimated using the Standardized Bycatch Reporting Methodology (SBRM) recommended in the GARM III Data meeting (GARM 2007, Wigley et al. 2007b). Observed ratios of discards of yellowtail flounder to kept of all species for large mesh otter trawl, small mesh otter trawl, and sea scallop dredge were applied to the total landings by these gears by half-year (Table 2). Uncertainty in the discard estimates was estimated based on the SBRM approach detailed in the GARM III Data meeting (GARM 2007, Wigely at al. 2007b). US discards were approximately $18 \%$ of the US catch in years 1994-2009 (Table 1; Fig. 2). Total discards of yellowtail in the US increased $93 \%$ from $2008(370 \mathrm{mt})$ to 2009 ( 715 mt ). This increase was due mainly to an increase in the large mesh discards (Table 2).

The total US catch of Georges Bank yellowtail flounder in 2009, including discards, was 1,689 mt. The US Georges Bank yellowtail flounder quota for fishing year 2009 (1 May 2009 to 30 April 2010) was set at $1,617 \mathrm{mt}$. Monitoring of the US catches relative to the quota was based on Vessel Monitoring Systems (VMS) and a call-in system for both landings and discards. Preliminary reporting on the Regional Office webpage (http://www.nero.noaa.gov/ro/fso/usc.htm) indicates the US fishery caught $109 \%$ of its quota for the 2009 fishing year.

## Canada

Canadian fishermen initiated a directed fishery for yellowtail flounder on Georges Bank in 1993. Prior to 1993, Canadian landings were low, typically less than 100 mt (Table 1, Fig. 2). Landings of $2,139 \mathrm{mt}$ of yellowtail occurred in 1994, when the fishery was unrestricted. After a TAC of 400 mt was established, yellowtail landings dropped to 464 mt in 1995. Subsequently, both quotas and landings increased and in 2001 landings reached a peak at $2,913 \mathrm{mt}$. The majority of Canadian landings of yellowtail flounder were made by otter trawl from vessels less than 20 m (tonnage classes 1-3). The fishery generally occurred from June to December, with most landings in the third quarter. Since 2004, there has been no directed Canadian fishery because fishermen have not been able to find commercial densities of yellowtail flounder. Landings have been less than 100 mt every year since 2004, with a low of 5 mt in 2009. In these years, most of the reported yellowtail landings were from trips directed for other groundfish species (i.e. cod or haddock).

The Canadian offshore sea scallop fishery is the source of Canadian yellowtail flounder discards on Georges Bank. As a result of the 2005 benchmark review, these data are now incorporated into the Canadian fishery catch and catch at age for 1973 onward (TRAC 2005). Discards are not recorded in the Canadian fishery statistics and are therefore estimated from observer deployments using the methodology documented in Van Eeckhaute et al. (2005). Since August 2004, there has been routine observer coverage on vessels in the Canadian scallop fishery on Georges Bank. A total of 5 trips were observed in 2004, 11 in 2005, 11 in 2006, 14 in 2007, 23 in 2008, and 21 in 2009. The seasonal pattern in bycatch rate is taken into account by applying calculations using 3 -month moving-average discard rates. Applying this approach to the 2009 data results in a discard estimate of 84 mt , the lowest value in the time series (Table 1, Fig. 2). Canadian discards were approximately $49 \%$ of the Canadian catch in years 1994-2009 (Table 1, Fig. 2).

The total Canadian catch of Georges Bank yellowtail flounder in 2009, including discards, was 89 mt , a decrease of $44 \%$ from 2008, and well below the 2009 TAC of 483 mt .

## Length and Age Composition

The level of US port sampling continued to be strong in 2009, with 12,408 length measurements available from 140 samples, resulting in 1,274 lengths $/ 100 \mathrm{mt}$ of landings (Table 3). This level of sampling resulted in low CVs for the US landings at age, as estimated by a bootstrapping procedure (Table 4). The 140 port samples also provided 2,883 age measurements for use in agelength keys. The Northeast Fisheries Observer Program provided an additional 12,810 length measurements of discarded fish from 207 trips, which were combined with the port samples to characterize the size composition of the US catch.

The US landings are classified by market category (large, small, medium, and unclassified) and this categorization is used to determine the size and age distributions. Both the amount and the proportion of yellowtail landed in the large market category have generally increased since 1995 (from approximately $50 \%$ to approximately $75 \%$ ). Examination of the size distributions of the two market categories continues to show some overlap in the $36-38 \mathrm{~cm}$ range, but overall each market group are distinctively separated (Fig. 3).

In 2009, no port samples were collected from the 5 mt of Canadian landings (Table 3). No length measurements were utilized from Canadian at sea observer deployments because sex determinations from these samples were found to be inaccurate.

US discard length frequencies were generated from observer data, expanded to the total weight of discards by gear type and half year. Large mesh trawl discards showed a strong peak near the minimum allowed size, but larger fish were also discarded (Fig. 4). Small mesh discards accounted for only a small portion of the total discards but cover a wide range of lengths because this fishery is prohibited from landing groundfish (Fig. 4). Scallop dredge discards were mainly legal sized fish, as has been typically seen for dredge gear in the past (Fig. 4).

The size composition of yellowtail flounder discards in the Canadian offshore scallop fishery was estimated by half year using length measurements obtained from 21 observed trips in 2009. These were prorated to the total estimated bycatch at size using the corresponding half year length-weight relationship and the estimated half year bycatch (mt) calculated using the methods of Stone and Gavaris (2005).

A comparison of the 2009 size composition of yellowtail catch by country shows the same proportional distribution at length for the landings (Fig. 5). This similarity is because there was no sampling of the Canadian landings and the assumption was made that the US and Canadian landings at length would be the same. US discards were quite similar in both mean size and spread in the distributions relative to Canadian discards (Fig. 6). The relative magnitude of landings and discards by each country resulted in total catch for Canada having a smaller average size than the total catch for the US (Fig. 7).

Although otoliths are used to determine ages for Grand Bank yellowtail (Walsh and Burnett 2001), age determination of Georges Bank yellowtail flounder using otoliths is hampered by the presence of weak, diffuse or split opaque zones and strong checks, which can make interpretation of annuli subjective and difficult (Stone and Perley 2002). Therefore, scales are the preferred structure for aging Georges Bank yellowtail flounder. Percent agreement on scale ages by the US readers continues to be high ( $>85 \%$ for most studies) with no indication of bias.

For the US fishery, sample length frequencies were expanded to total landings at size using the ratio of landings to sample weight (predicted from length-weight relationships by season; Lux 1969), and apportioned to age using pooled-sex age length keys in half year groups. Landings were converted by market category and half-year, while discards were converted by gear and half-year. The age length keys for the US landings used only age samples from US port samples. In the past, the age length keys for the US discards used age samples from at sea observers of the discarded catch supplemented with US surveys. Since 2004, the scales collected by the observers have not been aged and so only the US surveys provided ages. This year the resulting survey age distribution appeared unusually strong for a single age class, so the commercial ages were added
to the age length key. This had the effect of smoothing the age distribution and was deemed a better approach to forming the US discard at age. The US discards for years 2004-2008 were redone using both US surveys and US commercial ages. Although these years showed only minor changes in age distribution, these changes were incorporated in the catch at age data used for the assessment.

No scale samples were available for the Canadian fishery in 2009. Given the small amount of Canadian landings ( $5 \mathrm{mt}, 0.3 \%$ of the total catch), these landings were just apportioned to ages based on the US proportions of landings at age. The 2009 Canadian average weight at age for landed fish was assumed to be the same as the 2009 US average weight at age for landed fish. Canadian discards at age by half year were obtained using half year age length keys based on the following combined ages: Half 1 US commercial fishery + US spring survey + Canadian survey, and Half 2 US commercial fishery + US fall survey.

All discarded yellowtail flounder were assumed to die. This assumption of $100 \%$ discard mortality was examined in TRAC Working Paper 16 (Barkley et al. 2010) and found to be not influential in terms of stock status over a range from $0 \%$ to $100 \%$ discard mortality.

In 2009, ages 3 and 4 (2006 and 2005 year classes, respectively) dominated US landings and discards, with only minor contributions from Canadian catch (Fig. 8). Since the mid 1990s, ages 2-4 have constituted most of the exploited population, with very low catches of age 1 fish due to the implementation of larger mesh in the cod end of commercial trawl gear (Table 5; Fig. 9).

The fishery mean weights at age for each of the combinations of US and Canadian landings and discards were derived using the applicable age length keys, length frequencies, and lengthweight relationships. The mean weight at age (kg) for the US and Canadian landings were quite similar and generally were more variable at older ages (5+) during the mid 1980s to the mid 1990s. The overall fishery weight at age were calculated from US and Canadian landings and discards, weighting by the respective catch at age (Table 6; Fig. 10). A trend of increasing weight at age is apparent in both fisheries for all ages since 1995, returning to levels seen in the late 1970s/early 1980s. Recent weight at age (WAA) values are within both the range and one standard deviation of past WAA calculations since 1973.

## ABUNDANCE INDICES

Bottom trawl surveys are conducted annually on Georges Bank by Canadian Department of Fisheries and Oceans (DFO) in February (denoted spring) and by the US National Marine Fisheries Service (NMFS) in April (denoted spring) and October (denoted fall). The US NMFS scallop survey is conducted in June and catches a large number of yellowtail flounder, allowing it to be used as an additional tuning index. Both agencies use a stratified random design, though different strata boundaries are defined (Fig. 11). The NMFS spring and fall bottom trawl survey catches (strata 13-21), NMFS scallop survey catches (scallop strata 54, 55, 58-72, 74), and DFO spring bottom trawl survey catches (strata 5Z1-5Z4) were used to estimate relative stock biomass and relative abundance at age for Georges Bank yellowtail. Conversion coefficients, which adjust for survey door, vessel, and net changes in NMFS groundfish surveys ( 1.22 for old doors, 0.85 for the Delaware II, and 1.76 for the Yankee 41 net; Rago et al. 1994) were applied to the catch of each tow for years 1973-2008.

There continues to be high variability in the survey indices. Specifically, beginning in 2009 the US bottom trawl surveys were conducted with a new vessel, the FRV Henry B. Bigelow, which uses a different net and protocols from the previous survey vessels. Length-based conversion coefficients have been estimated for yellowtail flounder (see TRAC Working Paper 14; Brooks et al. 2010) and applied in this assessment to derive the survey catch at age (Table 7). The 2008 and 2009 Canadian surveys encountered individual tows that were much larger than any seen previously in the time series. The 2009 Canadian survey values at age have been updated from last year due to an incorrect expansion to the total area fished and missing ages in the age length key. The US assessment software has been upgraded to allow the 2009 TRAC recommendation to downweight the 2008 and 2009 Canadian survey values. The Canadian survey biomass index has changed from last assessment due to a miscommunication between US and Canadian scientists regarding the expansion from catch per tow to total biomass. However, these data are not used to calibrate the VPA and so have no impact on catch advice.

Given the lack of evidence for a strong dome in the partial recruitment of yellowtail flounder in the US scallop survey (see Working Paper 9, Legault et al. 2010), the US scallop survey was explored as a means of tuning all ages, instead of just as a recruitment index as has been done in the past. This approach was advanced in the 2009 TRAC meeting, but was not used because the 2008 US scallop survey did not cover the Canadian portion of Georges Bank. The length frequency distributions from the scallop survey were converted to ages by applying age length keys from the US spring and fall surveys combined. Comparison of the trends over time from the scallop and three bottom trawl surveys indicate they are tracking similar trends (Fig. 12a). Concern was expressed during the TRAC meeting that the scallop survey ages are smeared by using a combined spring and fall age-length key. Suggestions were made to either include the survey as an age $2+$ index, although age 2 would not be fully selected, or to use age length keys from commercial data instead. The TRAC agreed the scallop survey should be used for older ages in future assessments, but recommended the older ages not be included in the current assessment due to uncertainty in how variable the trends in older ages will be due to the approach used to age the length distributions.

Trends in yellowtail flounder biomass indices from the four surveys track each other quite well over the past two decades, with the exception of the DFO survey in 2008 and 2009 which were influenced by single large tows (Fig. 12b). The minimum swept area biomass estimated from the DFO survey increased from 1995 to 2001, declined through 2004, fluctuated through 2007, and then increased dramatically in 2008 and 2009 due single large tows in each year, as seen by the indices declining by about an order of magnitude when the single tows are excluded (Table 8a; Fig. 12b). The 2010 DFO biomass is close to the average of the time series when 2008 and 2009 are not included. The NMFS spring series was high in the mid 1970s, low in the late 1980s through mid 1990s, high from 1999 through 2003, sharply decreased in 2004, and has shown a recent increasing trend from 2004 through 2010 (Table 8b; Fig. 12b). The NMFS fall survey, which is the longest running time series, was high in the mid 1960s through mid 1970s, low in the mid 1980s through mid 1990s, increased through 2001, declined through 2005, and has remained at levels comparable to the late 1960s for the past three years, 2007-2009 (Table 8c; Fig. 12). The scallop survey stratified mean catch per tow shows a strong increase from low levels in the mid 1990s to a peak in 1998 followed by a decline through 2005, and has fluctuated since (Table 8d; Fig. 12b). Both the NMFS spring and fall survey indices show high inter-annual variability during the periods of high abundance (i.e. the 1960s and 1970s) which may reflect the
patchy distribution of yellowtail on Georges Bank and the low sampling density of NMFS surveys.

The distribution of catches (weight/tow) for the most recent year is compared with the previous ten year average for the three groundfish surveys in Figs. 13a-13b. Note the 2009 and 2010 NEFSC survey biomass values were adjusted from Bigelow to Albatross IV equivalents by dividing Bigelow catch in weight by 2.244 (spring) or 2.402 (fall), in contrast to the length specific conversion coefficients used to generate the age specific indices of abundance used for tuning the VPA (Table 7). This conversion of Bigelow survey biomass values is still under review and may change in the future. Since 1996, most of the DFO survey biomass and abundance of yellowtail flounder has occurred in strata 5 Z 2 and 5 Z 4 (Fig. 14a). However, in 2008 and 2009 almost the entire Canadian survey catch occurred in just one or two tows in stratum 5Z1, making interpretation of trends over time difficult. The 2010 DFO survey had a high proportion of the total catch in Stratum 5Z1 as well. The NEFSC bottom trawl surveys have been dominated by stratum 16 since the mid 1990s (Figs. 14b-14c). The apparent large differences in spatial distribution among surveys in the most recent year were discussed at length during the TRAC meeting. The use of different scales for US and Canada plots made direct comparison more difficult, but there are still apparently large changes in spatial distribution that can occur rapidly for this stock.

Age-structured indices of abundance for NMFS spring and fall surveys were derived using survey-specific age-length keys. In the past, age-length keys from NMFS spring surveys have been substituted to derive age composition for same-year DFO spring surveys, as no ages were available from the DFO surveys because of difficulties associated with age interpretation from otoliths (Stone and Perley 2002). To avoid having to use substituted age data, NMFS personnel have been ageing scales collected on DFO surveys since 2004 and continued to do so this year. From the 2010 DFO survey, 197 male and 170 female fish were aged and used to produce separate-sex age-length keys, subsequently used to generate the 2010 DFO age-specific indices of abundance.

Even though all four surveys initially indicated a strong 2005 year class, none of the surveys currently indicate the 2005 year class is particularly strong (Table 8; Figs. 15a-15f). Even though each index is noisy, the age specific trends track relatively well among the four surveys (Table 8; Fig. 16).

Trends in relative fishing mortality and total mortality from the surveys were examined as part of the consensus benchmark formulations agreed to at the second benchmark assessment meeting in April 2005. Relative fishing mortality (fishery catch biomass/survey biomass, scaled to the mean for 1987-2009) was quite variable but followed a similar trend for all four surveys, with a sharp decline to low levels since 1995 (Fig. 17). In contrast, estimates of total mortality rates from the surveys for ages 2,3 and 4-6, although noisy, are without trend and indicate no overall reduction in mortality since 1995 (Fig. 18). This disagreement between the relative F and survey Z trends lies at the heart of the retrospective pattern in this assessment. If fishing mortality has really decreased substantially since 1995, as indicated by the relative F pattern, why do we not see many old fish (ages $6+$ ) in the surveys or catch? This disagreement in the basic data causes the challenges for this assessment.

## ESTIMATION OF STOCK PARAMETERS

Results from assessment analyses conducted in recent years have displayed: a) retrospective patterns; b) residual patterns that are indicative of a discontinuity starting in 1995; and c) fishing mortality rates that are not consistent with the decline in abundance along cohorts evident in the survey data. Essentially, the catch at age data and assumed natural mortality rate cannot be reconciled with the high survey abundance indices at ages 2 and 3 and low survey abundance at ages 4 and older.

The empirical evidence suggests that significant modifications to the population and fishery dynamics assumptions are required to reconcile the fishery and the survey observations. Models that adopt such modifications imply major consequences on underlying processes or fishery monitoring procedures. The magnitude of implied changes to natural mortality rate, survey catchability relationships, or unreported catch is so great that the acceptability of models that incorporate these effects is suspect. However, these models may provide better catch advice for management of this resource than ignoring the changes in underlying processes (ICES 2008).

In view of these reservations, adoption of a benchmark formulation that incorporated these modifications to assumptions, as the sole basis for management advice was not advocated (TRAC 2005). Therefore the TRAC recommended that management advice be formulated after considering the results from three VPA approaches: Base Case, Minor Change, and Major Change. The Minor Change VPA was never used in any subsequent assessment (Stone and Legault 2005, Legault et al. 2006, Legault et al. 2007, Legault et al. 2008) and it was agreed during the 2009 TRAC that it would not be continued in the future (Legault et al. 2009). The Base Case VPA was continued for a number of years after the benchmark, but has not been accepted for use in providing management advice for the past few years (Legault et al. 2006, Legault et al. 2007, Legault et al. 2008, Legault et al. 2009). At the 2009 TRAC meeting, it was agreed that the Base Case model would no longer be considered in future assessments due to its strong retrospective pattern and inability to match trends observed in the surveys. To reduce confusion, the (modified) Major Change VPA is referred to as the Split Series VPA in this assessment, and is the default approach for providing management advice.

The VPAs are calibrated using the adaptive framework, ADAPT (Gavaris 1988) to calibrate the sequential population analysis with the research survey abundance trend results, specifically the NOAA Fisheries Toolbox VPA v3.0.3. The model formulation employed assumed error in the catch at age was negligible. Errors in the abundance indices were assumed independent and identically distributed after taking natural logarithms of the values. The exception to this assumption is the DFO survey values for 2008 and 2009 were downweighted (residuals multiplied by 0.5 ) to reflect the higher uncertainty associated with these observations relative to all other survey observations. Zero observations for abundance indices were treated as missing data, because the logarithm of zero is undefined. The annual natural mortality rate, M, was assumed constant and equal to 0.2 for all ages. The fishing mortality rates for age groups 4,5 and $6+$ were assumed equal. These model assumptions and methods were the same as those applied in the last assessment (Legault et al. 2009). Both point estimates and bootstrap statistics of the estimated parameters were derived using only the US software for this assessment.

The Major Change VPA recommended during the benchmark assessment expanded the ages from $6+$ to 12 , assumed a constant small number of fish (1000) survived to the start of age 13,
allowed power relationships between indices and population abundance for younger ages (1-3), and split the survey time series between 1994 and 1995. This model could not be fit well in previous assessments (Legault et al. 2006, Legault et al. 2007, Legault et al. 2008 ) due to a lack of catch at old ages creating bimodal bootstrap distributions. Following the precedent of previous assessments, the Major Change VPA was reformulated to be the same as the Base Case VPA, with the exception that the survey time series were split at 1995 (Legault et al. 2006, Legault et al. 2007, Legault et al. 2008, Legault et al. 2009). This means that indices and population abundance are assumed linearly related at all ages and that a $6+$ group is used for all fish aged 6 and older in the population dynamics equations. Splitting the survey series has been sufficient to remove the retrospective pattern and pattern in residuals, and was recommended for management advice because it more closely followed the pattern observed in the indices. This Split Series formulation was used again this year to provide management advice.

The Split Series VPA used revised annual catch at age (including US and Canadian discards), $C_{a, t}$, for ages $a=1$ to $6+$, and time $t=1973$ to 2009, where $t$ represents the beginning of the time interval during which the catch was taken. The VPA was calibrated to bottom trawl survey indices, $I_{s, a, t}$, for:
$s_{1}=$ DFO spring, ages $a=2$ to $6+$, time $t=1987$ to 1994
$s_{2}=$ DFO spring, ages $a=2$ to $6+$, time $t=1995$ to 2010
(note: $s_{2}=$ DFO spring, ages $a=2$ to $6+$, time $t=2008$ to 2009 residuals were downweighted)
$s_{3}=$ NMFS spring (Yankee 41), ages $a=1$ to $6+$, time $t=1973$ to 1981
$s_{4}=$ NMFS spring (Yankee 36), ages $a=1$ to $6+$, time $t=1982$ to 1994
$s_{5}=$ NMFS spring (Yankee 36), ages $a=1$ to $6+$, time $t=1995$ to 2010
$s_{6}=$ NMFS fall, ages $a=1$ to $6+$, time $t=1973.5$ to 1994.5
$s_{7}=$ NMFS fall, ages $a=1$ to $6+$, time $t=1995.5$ to 2009.5
$s_{8}=$ NMFS scallop, age $a=1$, time $t=1982.5$ to 1994.5
$s_{9}=$ NMFS scallop, age $a=1$, time $t=1995.5$ to 2009.5
(note: the NMFS scallop survey was not used for years 1986, 1989, 1999, 2000, or 2008)
Splitting the survey time series between 1994 and 1995 could not be justified based on changes in the survey design or implementation. Rather the split is considered to alias unknown mechanisms causing the retrospective pattern in the Base Case VPA. Relationships between indices and population abundance for all ages were assumed to be proportional. Population abundance at age 1 in the terminal year plus one (2010) was assumed equal to the geometric mean over the most recent 10 years (2000-2009). Population abundance in the terminal year plus one (2010) was estimated directly for ages 2-5.

## Building the Bridge

During the 2009 TRAC, the DFO surveys for 2008 and 2009 could not be down-weighted using the US software. The US software package has since been modified to allow this downweighting. It was expected that down-weighting the DFO surveys in 2008 and 2009 would produce results similar to an average of the two formulations recommended by the 2009 TRAC, which were considered to bracket the true population trajectory. The two 2009 TRAC formulations were denoted "Including", which treated these surveys as equivalent to all other survey observations (weight of one), and "Excluding" which did not include the 2008 or 2009 DFO survey observations at all (weight of zero). Applying the down-weighting approach to the
data used in the 2009 TRAC (labeled T09wted) did in fact result in values at nearly the average of the "Including" (labeled T09Inc) and "Excluding" (labeled T09Exc) runs (Figs. 19-20).

There were four additional changes to the data used in the 2009 TRAC:

1) The DFO 2009 survey values were adjusted (labeled T09wted_DFO2009)
2) The US landings for 2007 were adjusted (labeled T09wted_USland2007)
3) The US discards for 2004-2008 were adjusted (labeled T09wted_USdisc200408)
4) The calibration coefficients for the Bigelow became available allowing the use of the US spring 2009 survey (labeled T09wted_HBBSpr2009).

These four changes were examined one at a time relative to the TRAC 2009 weighted approach. The first three resulted in only minor changes, causing a slight decrease in 2008 spawning stock biomass (SSB) and slight increase in 2008 F, while the inclusion of the US spring 2009 survey had a larger impact reducing the 2008 SSB below and the 2008 F above the associated TRAC 2009 "Excluding" case (Figs. 19-20b). Due to the same directional change of all four changes, employing all four changes at once (labeled T09wted_all4) resulted in the lowest 2008 SSB and highest 2008 F , although the $80 \%$ confidence intervals of these estimates encompassed the TRAC 2009 weighted scenario (Figs. 20a-20b). This run (labeled T09wted_all4) which combined all four changes and used the down-weighting approach for the DFO 2008 and 2009 surveys was the starting point for the new assessment, which then added a year of catch and survey indices. These changes contribute to the historical retrospective pattern observed in this assessment.

## Diagnostics

The Split Series VPA performed similarly in terms of relative error and bias in the population abundance estimates to previous assessments with lower relative error and bias at older ages than younger ages (Table 9). This pattern of higher uncertainty in the younger ages has been seen in previous assessments and is due to having less information about these cohorts.

Survey calibration constants (q's) for the Split Series VPA also followed similar patterns to previous assessment (Table 9, Fig. 21). The most notable pattern was the increase in estimated values at nearly all ages between the pre-1995 and recent period (1995 to present), with some ages showing more than a five-fold increase and averaging a three-fold increase. There have been no changes in the survey design or operations that can explain such changes. These changes in q are considered to be aliasing unknown mechanisms and the series have been split for the sole purpose of producing a better fitting model. Management strategy evaluations have demonstrated that even if the true source of the retrospective pattern is misreported catch or changes in natural mortality, this approach of splitting the time series to address the retrospective problem produces better performance (true F closer to target F) than ignoring the retrospective pattern (ICES 2008).

The Split Series VPA residuals did not show a strong pattern, with mixed positive and negative residuals throughout the time series (Fig. 22). The plotted residuals for the 2008 and 2009 DFO survey account for the down-weighting used in the fitting, but still appear as strong positive residuals (observed values larger than predicted) except for the age $6+$ value in 2008. The standard sampling protocol in 2008 did not collect any age $6+$ yellowtail in the large tow that year, and so this index value was not high when the tow was included.

An alternative method to view the change in catchability is to plot the relative catchability (the survey observation divided by the estimated beginning of year population abundance) with the Split Series estimate of catchability overlaid as lines (Figs 23a-23c). These plots do not adjust the population abundance to account for the time of the survey. The changes in relative catchability appear strong and consistent for many surveys and ages, as opposed to being driven by just one or two outlier values. These consistent changes give more confidence to the approach of splitting surveys than changes due to one or two outliers would.

Retrospective analysis for the Split Series VPA did not indicate a strong tendency to over or underestimate fishing mortality on ages $4-5$ or recruitment, but did indicate a moderate tendency to overestimate SSB (Table 10, Figs. 24a-24b). The retrospective pattern for SSB is considerably less strong than has been seen in the Base Case formulations of previous assessments, where retrospective rho statistics of more than 1.0 were estimated, but should still be considered when providing management advice. The recruitment retrospective pattern is noisy with both positive and negative changes, but of most concern is the change to the 2005 year class which had been estimated as strong in the recent three peels and is now estimated as only average.

Despite the moderate retrospective pattern in SSB, the Split Series VPA is recommended as the basis for providing management advice.

## STOCK STATUS

Results from the Split Series VPA were used to evaluate the status of the stock in 2009 (Tables 11-12). The fishery weights at age, assumed to represent mid-year weights, were used to derive beginning of year weights at age (Table 13), and these were used to calculate beginning of year population biomass (Table 14). In the US, SSB is the legal status determination criterion and is computed assuming maturity at age and the proportion of mortality within a year that occurs prior to spawning $(p=0.4167)$.

Adult population biomass (age 3+) increased from a low of 2,100 mt in 1995 to $11,000 \mathrm{mt}$ in 2003, declined to about 2,900 mt in 2006, and increased to $14,600 \mathrm{mt}$ at the beginning of 2010, the highest adult biomass since 1974 (Table 14, Fig. 25). Total population biomass (age 1+) has generally tracked the three groundfish surveys, although splitting the series implies high catchability of the surveys in recent years (Table 14, Figure 26). Spawning stock biomass in 2009 was estimated to be $14,000 \mathrm{mt}(80 \%$ confidence interval: $11,700-17,100 \mathrm{mt})$. These 2009 values are well below both the TRAC 2009 Including and Excluding estimates for 2008 and reflect a change in the perception of the 2005 year class from strong to moderate. This change in perception of cohort strength has been seen in previous assessments and when it occurred it led to strong retrospective patterns.

During 1998-2001 recruitment averaged 22.2 million fish at age 1 but has since been below 20 million fish, with the exception of the 2005 and 2006 year classes estimated at 23.9 million and 22.2 million, respectively (Table 11). The 2007 year class is well below average, and the 2008 year class is estimated to be the lowest in the time series at 6.1 million. The strong change in perception of the strength of the 2005 year class is because it did not appear in any of the

2009-2010 surveys or the 2009 catch at the expected magnitude of a strong year class (Figs. 8 and 15 f ).

Fishing mortality for fully recruited ages $4+$ was close to or above 1.0 between 1973 and 1995, fluctuated between 0.51 and 0.97 during 1996-2003, increased in 2004 to 1.91, and then declined to 0.53 in 2007 and 0.15 in both 2008 and 2009 ( $80 \%$ confidence interval for 2009: 0.12-0.19), below the reference point of $\mathrm{F}_{\text {ref }}=0.25$ (Table 12). This pattern in F does not correspond with the relative fishing mortality rate pattern estimated as catch/survey (Fig. 17). The relative F pattern shows a sudden decline in 1995 and continued low levels since then. This pattern was seen in previous Base Case assessments. However, these assessments had strong retrospective patterns which increased the F as additional years became available. Given the lack of a strong retrospective pattern in the Split Series VPA for fishing mortality rate in this assessment, the 2008 and 2009 estimates of F are not expected to increase substantially with additional years of data.

## Sensitivity Analyses

Five sets of sensitivity analyses were conducted to explore the robustness of the Split Series formulation:

1. Including and Excluding formulations
2. VPA options
3. Surveys
4. Alternative approaches to reduce retrospective pattern
5. Natural mortality.

The TRAC 2009 "Including" and "Excluding" formulations had the expected results of higher SSB and lower F for the "Including" case and lower SSB and higher F for the "Excluding" case, although both were within the $80 \%$ confidence intervals of the Split Series results (Figs. 27a28b). These runs confirmed that down-weighting the 2008 and 2009 DFO surveys by $50 \%$ resulted in SSB and fishing mortality rates approximately halfway between the full weighting and zero weighting.

The second set of sensitivity analyses explored options available within the US VPA software. The Split Series formulation used the Backward solution to calculate the plus group, which results in the same F for ages 4, 5, and 6 each year, but can result in unfeasible plus group abundances (the plus group in year $t$ is greater than the sum of the plus group and last full age in year $t-1)$. No unfeasible solutions were found in the Split Series VPA. The US VPA software also allows Forward and Combined solutions to the plus group, which differ by the Forward solution allowing the F on the plus group to be quite different from the F on oldest true age, while the Combined solution disassociates the F on the oldest true age from younger ages. The Forward option resulted in higher SSB and lower F than the Split Series while the Combined option resulted in lower SSB and higher F than the Split Series, with both near the $80 \%$ confidence interval values (Figs. 28a-28b). These options also caused minor changes to the historical estimates of SSB and F. The distinction between these methods can be seen by examining ratios of successive ages in the estimate F matrix. The ratio of age $6+$ to age 5 F in the Forward option shows a strong dome for years 1980 through 2000 followed by two large spikes in 2004 and 2006 when the age $6+F$ was greater than 4 (Fig. 29). In contrast, the Combined option has the same F at ages 5 and $6+$, but can vary between ages 4 and 5 . The ratio of age 5 to
age 4 F in the Combined option is quite stable and close to one (Fig. 29). Another US VPA setting that was explored was to estimate the age $6+$ abundance at the start of 2011. This resulted in slightly higher SSB and slightly lower F than the Split Series run which did not estimate this age group, but the results were well within the $80 \%$ confidence bounds of the Split Series VPA (Figs. 28a-28b). The uncertainty on this additional parameter was relatively high (57\%) and so the addition of this parameter could not be justified.

The third set of sensitivity analyses used only one survey at a time as tuning indices (Figs. 28a28b). The US scallop survey used all ages for this sensitivity run, as opposed to using only age 1 as in the Split Series VPA. Using only the US spring survey to tune the VPA resulted in lower SSB and higher F than the Split Series, just outside the $80 \%$ confidence intervals, while using only the US fall survey to tune the VPA resulted in higher SSB and lower F than the Split Series VPA, well outside the $80 \%$ confidence intervals. In contrast, the DFO survey was well within the $80 \%$ confidence intervals, with slightly lower SSB and higher F than the Split Series VPA. Using only the US scallop survey produced the lowest SSB and highest F of all the sensitivity runs. This extreme result may be due to the missing 2008 values causing the model difficulty in estimating stock abundance parameters (CVs ranged from $53 \%$ to $83 \%$ ). When ages 2 through $6+$ are included in the US scallop survey along with all the other survey values, the SSB is at the lower $80 \%$ confidence interval and F is at the upper $80 \%$ confidence interval of the Split Series VPA. A final run in this set dropped all 2010 survey information, meaning the US spring survey and DFO survey values for 2010. This resulted in a higher SSB and lower F than the Split Series VPA, near the $80 \%$ confidence intervals. In summary, the US spring and scallop surveys are pushing the model towards a lower SSB and higher F, the US fall survey is pushing the model towards a higher SSB and lower F, and the DFO survey is tracking fairly well the combined Split Series VPA.

The fourth set of sensitivity analyses examined alternative ways to remove the retrospective pattern, specifically by estimating additional catch or natural mortality in recent years. In order to do this, the surveys first had to be put back into single series (e.g. eliminate the split and treat the surveys as continuous for all years available, except for the US spring Yankee 41 net). This was done and resulted in much higher SSB and much lower F than the Split Series VPA (Figs. 28a28b). The single series run also exhibited a strong retrospective pattern, with rho of 1.36 and 0.55 for SSB and F, respectively. Using the catch multiplier option in the US VPA software resulted in much higher catch for most years since 1995, with five years hitting the user defined bound of five (meaning catch at age in those years was multiplied by five). This changed not only the SSB and F in 2009, but also the historical trends as well (this run has SSB > 30,000 mt in year 2000, Fig. 27a). This run had a much higher SSB in 2009 and a much higher F in 2009 than the Split Series VPA. The F in 2009 is well above the $\mathrm{F}_{\text {ref }}$ of 0.25 . This run had a substantially reduced retrospective pattern, with rho of 0.45 and -0.09 for SSB and F, respectively. The other approach to reduce the retrospective pattern is to increase M in the recent years, since 1995. An exploratory analysis over a range of M values found the best fit for $\mathrm{M}=0.6$ in years 1995 through 2009 at all ages, while keeping the M at 0.2 for earlier years. This run also substantially changed the historical time series of SSB and F (Figs. 27a-b) and resulted in higher 2009 SSB and lower 2009 F than the Split Series VPA. This run also reduced the retrospective pattern, with rho $=0.62$ and -0.28 for SSB and F, respectively. These examples demonstrate that alternative methods can be used to reduce the retrospective pattern. However, a full analysis of these alternative approaches to reducing the retrospective pattern would require calculation of reference points and comparison of projected and realized yields, which time did not permit.

These alternatives also imply that catch is seriously underestimated, in either landings, discards, or both, or that natural mortality has changed suddenly and dramatically, neither of which can be supported by any empirical evidence.

The final set of sensitivity analyses examined changes to the full natural mortality matrix. The same value of M was used for all years and ages for a range of values from 0.05 to 0.80 in steps of 0.05 . The minimum residual sum of squared residuals was found at $\mathrm{M}=0.2$ and 0.25 (same RSS for these two M). As expected, increasing M led to increased estimates of N and SSB and decreased estimates of F. However, the model did not perform better, in terms of model fit, with an increased or decreased M relative to the Split Series VPA.

These sensitivity analyses demonstrate the Split Series VPA is generally robust to model assumptions and choices of data used, although the $80 \%$ confidence intervals may not fully capture the total uncertainty in the assessment (as described in the Outlook section).

## FISHERY REFERENCE POINTS

## Yield per Recruit Reference Points

The current reference fishing mortality rate used by the TMGC ( $\mathrm{F}_{\text {ref }}=0.25$, ages $4+$ ) was derived from both $\mathrm{F}_{0.1}$ and $\mathrm{F}_{40 \% \mathrm{MSP}}$ calculations. Although the yield per recruit (YPR) analysis was not updated this year, both the 2002 and 2008 assessment YPR analysis (NEFSC 2002, NEFSC 2008 confirmed that both these values remain at 0.25 . This is the same value as the $\mathrm{F}_{\text {MSY }}$ proxy of $\mathrm{F}_{40 \% \mathrm{mSP}}$ used for US management (NEFSC 2008). This suggests that $\mathrm{F}_{\text {ref }}$ is robust to the changes in partial recruitment observed over the years.

## Stock and Recruitment

The TMGC does not have an explicit biomass target. There is evidence of reduced recruitment at low levels (below $5,000 \mathrm{mt}$ ) of SSB (Fig. 30). In the US, a similar stock-recruitment relationship from the GARM assessment (NEFSC 2008) was used to estimate the $\mathrm{B}_{\text {MSY }}$ proxy by projecting the population for many years with $\mathrm{F}=\mathrm{F}_{40 \% \mathrm{MSP}}$ and recruitment randomly selecting from the cumulative distribution function of recruitment observed at $\mathrm{SSB}>5,000 \mathrm{mt}$. The $\mathrm{B}_{\mathrm{MSY}}$ level of $43,200 \mathrm{mt}$ of SSB was set as the rebuilding goal in the US for this stock (NEFSC 2008). Current levels of SSB are below the rebuilding goal $\left(\mathrm{SSB}_{2009} / \mathrm{SSB}_{\mathrm{MSY}}=32 \%\right)$.

## OUTLOOK

This outlook is provided in terms of consequences with respect to the harvest reference points for alternative catch quotas in 2011. Uncertainty about current biomass generates uncertainty in forecast results, which is expressed here as the risk of exceeding $\mathrm{F}_{\text {ref }}=0.25$. The risk calculations assist in evaluating the consequences of alternative catch quotas by providing a general measure of the uncertainties. However, they are dependent on the data and model assumptions and do not include uncertainty due to variations in weight at age, partial recruitment to the fishery, natural mortality, systematic errors in data reporting or the possibility that the model may not reflect stock dynamics closely enough.

Due to recent trends in fishery partial recruitment patterns and survey and fishery weights at age, average values from 2007-2009 were used in the projections. As has been done in the past TRAC assessments, recruitment for the deterministic projections was set as the geometric mean of the previous ten years (1999-2008; 13.707 million age-1 fish) while stochastic projections use the two stage empirical cumulative distribution function of recruitment estimates from GARM 3 used to set the US rebuilding target (median recruitment of 24.6 million age-1 fish). These differences in recruitment assumption have only minor impact on 2011 projected catch, but would have large impact on medium or long term projections.

Assuming a catch in 2010 equal to the $1,956 \mathrm{mt}$ (the sum of the individually determined quotas for USA and Canada), a combined US/Canada catch of about 3,400 mt in 2011 would result in a neutral risk $(\sim 50 \%)$ that the fishing mortality rate in 2011 will exceed $\mathrm{F}_{\text {ref }}$, while catches of 3,100 mt and $3,800 \mathrm{mt}$ in 2011 would result in $25 \%$ and $75 \%$ risk that fishing mortality rate will exceed $\mathrm{F}_{\text {ref }}$, respectively (Fig. 31). Fishing at $\mathrm{F}_{\text {ref }}$ in 2011 will generate no change in age 3+ biomass from 2011 to $2012(15,200 \mathrm{mt}$, Table 15). A catch in 2011 of $3,400 \mathrm{mt}$ will result in no change in median biomass from 2011 to 2012, while catches in 2011 of $1,900 \mathrm{mt}$ and 400 mt will result in $10 \%$ and $20 \%$ increases in median biomass from 2011 to 2012, respectively (Fig. 31).

Although not as strong as initially estimated, the survival of the 2005 year class has been good and this year class will enter the plus group in 2011. The average weight of yellowtail flounder in the plus group would be expected to decrease when the 2005 year class enters in 2011. As a sensitivity analysis, the average weight for the plus group in the catch was reduced from 0.962 (the three year average of the plus group) to 0.918 (the three year average of age 6 fish). In the deterministic projections, this reduction led to a loss of 65 mt of yield ( $<2 \%$ change) in 2011.

In the US, there is a requirement to provide rebuilding projections when stocks are overfished. The rebuilding scenario for Georges Bank yellowtail flounder requires solving for a value of F (Freb75) that, when applied in years 2011-2014, results in a $75 \%$ probability that SSB in 2014 is greater than SSBmsy ( $43,200 \mathrm{mt}$ ). Using the same starting conditions as the projection described above, it was determined that even an F of zero was insufficient, with only $36 \%$ probability of SSB being above the SSBmsy target (Table 16). Three options are currently under consideration to replace this rebuilding scenario:
A) Rebuild by 2016 with $50 \%$ probability
B) Rebuild by 2016 with $60 \%$ probability
C) Rebuild by 2016 with $75 \%$ probability.

Applying a constant fishing mortality rate during years 2011 to 2020 in the range of 0.04 to 0.15 allowed determination of appropriate rebuilding F values for each of these options: $\mathrm{F}=0.14$, 0.10 , and 0.04 for options A, B, and C, respectively (Table 16). The distribution of catch under these rebuilding strategies was compared with the distribution of catch when $\mathrm{F}_{\text {ref }}$ was applied in 2011 and $75 \%$ of $\mathrm{F}_{\text {ref }}$ was applied in 2011 (Table 17). These distributions were quite different as seen by the lack of overlap of the $90 \%$ confidence intervals for many of the strategies, with the absolute range of median catch approximately $2,000 \mathrm{mt}$.

Alternative projection assumptions were explored to examine the sensitivity of catch advice. The population abundance at age in 2010 was adjusted to account for the retrospective pattern in two
different ways; adjust all ages by the same amount based on the SSB retrospective rho or adjust each age according to its own retrospective rho. The SSB rho is 0.41 which means that each stock abundance at the start of 2010 is multiplied by $1 /(1+0.41)=0.70922$. The age specific rho adjustments and associated multipliers for the start of 2010 stock abundance varied by age

|  | age1 | age2 | age3 | age4 | age5 | age6+ |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: |
| rho | 0.40 | 0.40 | 0.68 | 0.98 | 0.21 | 0.62 |
| multiplier | 0.714286 | 0.714286 | 0.595238 | 0.505051 | 0.826446 | 0.617284 |

These two approaches to adjust projections for retrospective patterns produced similarly reduced 2011 catch advice relative to the Split Series VPA (Table 18, Fig. 31). Additionally, these two retrospective adjustments to the projections resulted in none of the rebuilding options being possible, fishing at $\mathrm{F}=0$ resulted in $75 \%$ or less probability of achieving rebuilding by 2016 (Table 19).

A second set of sensitivity projections sampled recruitments for the stochastic projections from a distribution of estimated age 1 abundance for years 1983 to 2009. This set of recruitments had a median of 14.1 million in contrast to the standard rebuilding projections which had a median of 24.6 million, which uses recruitment estimates from 1963 to 2007 (Table 20). Although catch advice for 2011 was unchanged (Table 20), the probability of achieving US rebuilding targets was reduced, e.g. under no fishing there is less than a $5 \%$ probability of $\mathrm{SSB}_{2020}>43,200 \mathrm{mt}$ (note that SSBmsy assumes a median recruitment of 24.6 million, Table 21). Median catch in projected years diverged from the standard $\mathrm{F}_{\text {ref }}$ projections beginning in 2014 and were less than half the standard projections by 2020 (Table 21).

Age structure, fish growth, and spatial distribution reflect stock productivity. The current age structure indicates that very little rebuilding of ages 6 and older has occurred (Fig. 32). The 2009 population abundance proportions at age were above the values expected in equilibrium at $\mathrm{F}_{\text {ref }}$ for ages 3,4 , and 5 , but this is partially due to being well below the expected proportions at ages 1 and 2. Far fewer older fish $(6+)$ are estimated in the VPA in comparison with the population at equilibrium, which is inconsistent with the perception of recent low exploitation from the relative F calculations. The spatial distribution patterns from the DFO survey are difficult to interpret due to the large DFO tows in 2008 and 2009. These individual large tows could be indicative of a change in behavior of this species on Georges Bank, although they have not occurred in any of the NEFSC surveys and did not occur in 2010. Truncated age structure in the surveys and change in distribution indicate current productivity may be limited relative to historical levels.

## MANAGEMENT CONSIDERATIONS

This assessment is hampered by inconsistencies between the age structure of the catch and the age-specific indices of abundance. Although the catch of old fish has increased in recent years, it is still less than would be expected given the increases seen in the age-specific indices of abundance. The noisy character of the indices cause difficulty in tuning age structured models.

Although the Split Series VPA is used for management decisions, the mechanisms for the large changes in survey catchability are not easily explained. These changes in survey catchability are most appropriately thought of as aliasing an unknown mechanism that produces a better fitting
model. The inability to plausibly explain these survey catchability changes causes increased uncertainty in this assessment relative to other assessments. Although the intention of the split series VPA was to eliminate the retrospective pattern, the pattern has re-emerged but at a lower magnitude primarily due to change in perception of the 2005 year class.

Consistent management by Canada and the US is required to ensure that conservation objectives are not compromised.

The change in perception of this stock from previous assessments can be seen by examining the historical retrospective analysis, which plots the results from previous assessments instead of peeling back years from the current assessment (Fig. 33). The historical retrospective analysis incorporates all data and model formulation changes as well as the number of years in the assessment. The change in the strength of the 2005 year class (shown at age-1 in 2006 in the recruitment panel) is the cause of the change in perception, similar to the assessment retrospective analysis. The reduction in the 2005 year class translates into a reduced SSB and a higher fishing mortality rate than estimated in previous assessments. As noted in the 2009 TRAC assessment referring to the 2005 year class "The results of next year's assessment should indicate whether or not this strong cohort continues to contribute significantly to the adult and spawning stock biomass." Since none of the surveys now determine the 2005 year class to be strong, and the catch was not dominated by this year class in the past year, the model estimates an average instead of strong 2005 year class.

Another way to examine the impact of the change in perception of the 2005 year class is to compare the proportion of yield and biomass expected from this year class from projections of previous assessments with that now estimated. In the 2009 assessment, the 2005 year class was expected to account for $58-59 \%$ of the 2009 catch (in weight), $47-51 \%$ of the 2010 catch, and $40-$ $44 \%$ of the 2010 age $3+$ biomass. The current assessment estimates the 2005 year class to account for $40 \%$ of the 2009 catch, $33 \%$ of the 2010 catch, and $32 \%$ of the 2010 age $3+$ biomass, demonstrating that the 2005 year class is not as strong as previously estimated.

Table 7. Length based calibration factors for yellowtail flounder (see Brooks et al. 2010 for details of derivation). Numbers at length from Henry Bigelow tows should be divided by the calibration factor in the corresponding length bin. It is recommended that these calibration factors be applied with all 6 digits to the right of the decimal point.

| Length | Calibration |
| :---: | ---: |
| $\leq 18$ | 3.857302 |
| 19 | 3.857302 |
| 20 | 3.857302 |
| 21 | 3.621597 |
| 22 | 3.385892 |
| 23 | 3.150187 |
| 24 | 2.914482 |
| 25 | 2.678777 |
| 26 | 2.443072 |
| 27 | 2.207367 |
| 28 | 1.971662 |
| 29 | 1.971657 |
| $\geq 30$ | 1.971657 |

Table 8a. DFO spring survey indices of minimum swept area abundance for Georges Bank yellowtail flounder in thousands of fish and thousands of metric tons. Note that two vectors are presented for 2008 and 2009: 2008a and 2009a include the large tows while 2008b and 2009b do not.

Table 8d. NEFSC scallop survey index of abundance (stratified mean \#/tow in numbers) for Georges Bank yellowtail flounder and index of total biomass (stratified mean kg/tow). Note the values for 1989 and 1999 are considered too uncertain for use as a tuning index and the 1986, 2000, and 2008 surveys did not fully cover the Canadian portion of Georges Bank (D. Hart, pers. comm.).

Table 17. Percentiles of the distributions of catch (mt) in 2011 under a range of strategies for rebuilding or harvest rates. The first four strategies correspond to US rebuilding options where year denotes the time and P (reb) the probability when the spawning stock biomass should be greater than $43,200 \mathrm{mt}$. The median catch values are bolded. Relative Change in B denotes the relative change in age 3+ Jan-1 biomass from 2011 to 2012 (used as a measure of the risk of stock increase).

| Strategy | Year | P(reb) | F | Catch 2011 (mt) |  |  |  |  |  |  |  |  | Relative Change B |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

## 2009

Figure 8. Catch at age of Georges Bank yellowtail flounder in 2009 from the four components of Canadian and US landings and discards.

Catch at Age

Figure 9. Catch at age for Georges Bank yellowtail flounder, Canadian and USA fisheries combined. (The area of the bubble is proportional to the magnitude of the catch). Diagonal red lines denote the 1975, 1985, 1995, and 2005 year classes.

Figure 10. Trends in mean weight at age from the Georges Bank yellowtail fishery (Canada and USA combined, including discards). Dashed lines denote average of time series.

Figure 11. NMFS (top) and DFO (bottom) strata used to derive research survey abundance indices for Georges Bank groundfish surveys. Note NMFS stratum 22 is not used in assessment.

Figure 11. (continued) NMFS scallop survey strata used to derive research survey abundance indices.

Figure 12a. Four survey biomass indices for yellowtail flounder on Georges Bank rescaled to their respective means for years 1987-2005.

Figure 12b. Survey biomass for yellowtail flounder on Georges Bank in units of thousand metric tons (DFO, NEFSC spring, NEFSC fall, all three are minimum swept area biomass values) or $\mathrm{kg} /$ tow (NEFSC scallop, stratified mean catch per tow).

Figure 13a. Catch of yellowtail in weight (kg) per tow for DFO survey. Left panel shows previous 10 year averages, right panel most recent data.

## Georges Bank Yellowtail Flounder NEFSC Spring Survey

Georges Bank Yellowtail Flounder NEFSC Fall Survey

Figure 13b. Catch of yellowtail in weight (kg) per tow for NEFSC spring and NEFSC fall surveys. Left panels show previous 10 year averages, right panels most recent data. Note the 2009 and 2010 survey values were adjusted from Bigelow to Albatross IV equivalents by dividing Bigelow catch in weight by 2.244 (spring) or 2.402 (fall).

Figure 14a. DFO spring survey estimates of total biomass (top panel) and total abundance (bottom panel) by stratum area for yellowtail flounder on Georges Bank.

NEFSC Spring

Figure 14b. NEFSC spring survey estimates of total biomass (top panel) and proportion (bottom panel) by stratum for yellowtail flounder on Georges Bank.

NEFSC Fall

Figure 14c. NEFSC fall survey estimates of total biomass (top panel) and proportion (bottom panel) by stratum for yellowtail flounder on Georges Bank.

## DFO (Including)

Figure 15a. Age specific indices of abundance for the DFO spring survey including the large tows in 2008 and 2009 (the area of the bubble is proportional to the magnitude). Diagonal red lines denote the 1965, 1975, 1985, 1995, and 2005 year classes.

## DFO (Excluding)

Figure 15b. Age specific indices of abundance for the DFO spring survey excluding the large tows in 2008 and 2009 (the area of the bubble is proportional to the magnitude). Diagonal red lines denote the $1965,1975,1985,1995$, and 2005 year classes.

## Spring

Figure 15c. Age specific indices of abundance for the NMFS spring survey (the area of the bubble is proportional to the magnitude). Diagonal red lines denote the 1965, 1975, 1985, 1995, and 2005 year classes.

## Fall

Figure 15d. Age specific indices of abundance for the NMFS fall survey (the area of the bubble is proportional to the magnitude). Diagonal red lines denote the 1965, 1975, 1985, 1995, and 2005 year classes.

## Scallop

Figure 15e. Age specific indices of abundance for the NMFS scallop survey, note years 1986, 1989, 1999, 2000, and 2008 are not included (the area of the bubble is proportional to the magnitude). Diagonal red lines denote the 1965, 1975, 1985, 1995, and 2005 year classes.

Figure 15f. Age specific indices of abundance for the recent years of the four surveys, note year 2008 is not included in the scallop plot (the area of the bubble is proportional to the magnitude). The red diagonal line denotes the 2005 year class.

Figure 16. Standardized catch/tow in numbers at age for the four surveys plotted on natural log scale. The standardization was merely the division of each index value by the mean of the associated time series. Squares denote the DFO survey, triangles the NEFSC spring survey, open circles the NEFSC fall survey, and closed circles the NEFSC scallop survey.

Figure 17. Trends in relative fishing mortality (catch biomass/survey biomass), standardized to the mean for 1987-2009.

Figure 18. Trends in total mortality $(Z)$ for ages 2,3 , and 4-6 from the four surveys.

## Bridge Building

Figure 19. Spawning stock biomass (mt, top panel) and fishing mortality rate (ages $4+$, bottom panel) for the TRAC 2009 assessment and four data updates since then (see text for details).

Figure 20a. Spawning stock biomass (mt) in 2008 from the TRAC 2009 assessment and four data updates since then (see text for details). The vertical dashed red line denotes the average of the two TRAC 2009 assessments. The vertical dotted blue lines denote the $80 \%$ confidence interval for the run with all four updates (T09wted_all4).

Figure 20b. Fishing mortality rate (ages 4+) in 2008 from the TRAC 2009 assessment and four data updates since then (see text for details). The vertical dashed red line denotes the average of the two TRAC 2009 assessments. The vertical dotted blue lines denote the $80 \%$ confidence interval for the run with all four updates (T09wted_all4).

Figure 21. Catchability coefficients ( $q$ ) from the Split Series VPA with bootstrapped $80 \%$ confidence intervals.

Figure 22. Georges Bank yellowtail flounder age by age residuals from the Split Series VPA for In abundance index minus $\ln$ population numbers (bubble size is proportional to magnitude). The red symbols denote negative residuals, and white symbols denote positive residuals.

Figure 23a. Age specific relative catchability plots (survey index divided by the estimated abundance in numbers at that age and year) for the NEFSC spring survey. Horizontal bars denote the estimated catchability value from the Split Series VPA. No adjustments have been made to the estimated abundance to account for the timing of the survey.

Figure 23b. Age specific relative catchability plots (survey index divided by the estimated abundance in numbers at that age and year) for the NEFSC fall survey. Horizontal bars denote the estimated catchability value from the Split Series VPA. No adjustments have been made to the estimated abundance to account for the timing of the survey.

Figure 23c. Age specific relative catchability plots (survey index divided by the estimated abundance in numbers at that age and year) for the NEFSC scallop survey (age 1) and DFO survey (ages 2-6+). Horizontal bars denote the estimated catchability value from the Split Series VPA. No adjustments have been made to the estimated abundance to account for the timing of the survey.

Figure 24a. Retrospective analysis of Georges Bank yellowtail flounder from the Split Series VPA for age $4+$ fishing mortality (top panel), spawning stock biomass (middle panel), and age-1 recruitment (lower panel).
