#### Abstract

An abundance index of Atlantic mackerel (Scomber scombrus L.) is calculated using data from a U.S. bottom trawl survey, which is conducted annually in the region between Cape Hatteras and Georges Bank. This index is supposed to represent the abundance of these two mackerel contingents in the northwest Atlantic. Point kriging was used on the catch data from this survey to measure the respective abundance of each contingent, assuming that the $70^{\circ}$ west meridian represents their respective limit. The geographic distribution of catch data as well as the kriging results shows that the most numerous and most significant mackerel catches were generally associated with the area west of this limit and with the south contingent. These results also raise questions about the representativeness of fish from the north contingent in the American index, the validity of using this index in the abundance assessment of both contingents and the lack of information concerning the distribution and migration patterns of Atlantic mackerel in the northwest Atlantic.

## RÉSUMÉ

Un indice d'abondance du maquereau bleu (Scomber scombrus L.) est calculé à partir des données d'un relevé américain au chalutage de fond qui est réalisé annuellement dans la région située entre Cape Hatteras et le Banc George. Cet indice est supposé représenter l'abondance des deux contingents de maquereau présents dans le nord-ouest de l'Atlantique. Le krigeage ponctuel a été utilisé sur les données de captures de ce relevé afin de mesurer l'abondance respective de chaque contingent en assumant que le méridien de $70^{\circ}$ ouest représente leur limite respective. La distribution géographique des données de captures de même que les résultats du krigeage démontrent que les plus nombreuses et les plus importantes captures de maquereau étaient généralement associées à la zone située à l'ouest de cette limite et au contingent sud. Ces résultats soulèvent aussi des questions quant à la représentativité des poissons du contingent nord dans l'indice américain, sur la validité d'utiliser cet indice dans l'évaluation d'abondance des deux contingents et sur le manque d'information concernant les patrons de distribution et de migration du maquereau bleu dans le nord-ouest de l'Atlantique.

## INTRODUCTION

"It is very difficult to manage a stock that keeps on changing its distribution, particularly when nobody knows precisely where the entire stock is throughout the year or where it is likely to be in the next few years. I've always had sympathy with the managers on this one!"

Molloy (2004) concerning the Atlantic mackerel in the Northeast Atlantic.

## Stock Identification and Definition

The identification of ocean fish stocks is a fundamental pre-requisite to any abundance evaluation program and fisheries management (Cadrin et al. 2005, Molloy 2004). In fact, most models used in population dynamics assume that the group of fish under study has similar biological characteristics and a life cycle that enables young individuals to be produced by adults from the same group. A stock is defined as a population of organisms which, sharing a common gene pool with neighbouring stocks, is sufficiently discrete to warrant consideration as a self-perpetuating (Larkin 1972). Ihssen et al. (1981) defines a stock as an intraspecific group of randomly mating individuals with temporal or spatial integrity. Hilborn and Walters (1992) define a stock as a group of fish having the same biological characteristics and whose numbers are high enough to self-reproduce. Finally, Cushing (1968) defines an "ideal" fish stock as one that has a single spawning ground to which the adults return year after year.

There are two main approaches for identifying or defining ocean fish stocks (Hare 2005). A stock that is defined by a genotypic approach is characterized by individuals of a given species that breed among themselves and whose genetic integrity is ensured upon spawning by spatial or temporal isolation. At certain times of the year, these individuals can be mixed with those belonging to another stock. However, a stock that is defined by a phenotypic approach differs from another by the expression of certain meristic or morphological characteristics due to some environmental or genetic factors.

A stock can also be defined by a third approach, the contingent originally proposed by Clark (1968) and repeated more recently by Secord (1999). According to these authors, a contingent would be a group of individuals with spatial and temporal integrity due to a distinctive migration pattern. Hare (2005) mentions that the contingent concept is interesting because it reflects the same basic principles that served to define the hypotheses dealing with the structure of ocean fish populations (triangle migration, member-vagrant, basin model and migration loop hypotheses).

## Atlantic Mackerel in the Northwest Atlantic

Sette (1950) is one of the first to examine the differentiation of mackerel (Scomber scombrus L.) in the northwest Atlantic. From a large number of commercial samples collected between 1926 and 1935, Sette (1950) observed differences between the lengths of Atlantic mackerel caught in U.S. and Canadian waters (Appendix 1). He also observed a slower growth in fish caught in U.S. waters. Based on these observations and on results from various tagging projects, and on the presence of two spawning sites and distinct migration patterns, Sette suggested the presence not of two stocks, but of two groups or contingents of mackerel in the northwest Atlantic. He did not establish any genetic distinction between these groups, but he did however mention the possibility.

Since Sette, various research has been conducted from meristic data (MacKay and Garside 1969), the daily otolith growth pattern during the first year of life (Simard et al. 1992) and their
form (Castonguay et al. 1991) to describe and attempt to distinguish between the two contingents. However, genetic differences have been suggested by studies on the polymorphism of some proteins (MacKay 1967, Maguire et al. 1987). More recently, phylogenetic and molecular variance analysis (AMOVA) did not reveal genetic differences between the northern and southern contingents (Lambrey de Souza et al. 2006). This lack of apparent difference could be explained by the occurrence of mixing between the two contingents, by the very high variability of the studied mtDNA fragment or by the small sample size (Lambrey de Souza et al. 2006).

## Distribution and Migration

## Sette's Perspective (Sette 1950)

According to commercial fishery data available to Sette, Atlantic mackerel of the northwest Atlantic are found from North Carolina to Newfoundland. Some catches are made along the southern and western coasts of Newfoundland, but not enough to support a regular fishery. During the fishing season, mackerel distribution extends from Chesapeake Cape north to the Magdalen Islands and the Gaspé Peninsula.

Also according to commercial fishery data available to Sette, the first mackerel appear in early April in the area between Chesapeake and Delaware Capes. In April and May, individuals move closer to the coast and then travel to New England. These movements are associated with warmer surface temperatures. At about the same period, mackerel appear along the coast of Nova Scotia. During the following 2 - weeks, schools of mackerel travel to and frequent the Gulf of Maine and the southern Gulf of St. Lawrence where they remain until September. The schools leave the northernmost regions and travel south in October and November before leaving the coasts in December. Juveniles have a different migration pattern, preferring coastal waters where they stay until late in the season (December). Winter habitats are found in deep waters and on the edge of the continental shelf between Cape Hatteras and the southern edge of Georges Bank and possibly up to Sable Island. Individuals from the southern contingent can be found in the southern portion of this area and individuals from the northern contingent in the northern portion.

In the spring, individuals from the northern contingent likely travel from the Hudson Channel, and as they near the coast, they mix with the southern contingent over a short period of time. According to length frequency data, individuals from the northern contingent are larger. Successive waves from offshore join the main front moving eastward and along the coast of Nova Scotia. In the fall, individuals from both contingents likely migrate in the opposite direction. The two contingents likely mix for a second time north of Nantucket Shoals and of the spring mixing area.

Recent commercial fishery data is generally consistent with the above description. However, mackerel now occur in larger numbers and over a longer period of time on the three coasts of Newfoundland and in Labrador.

## Stock Assessment

## Canadian Contingent

A spawning biomass index of individuals from the northern contingent has been evaluated since 1983 using an egg survey (Maguire 1979, 1980, 1981; Ouellet 1987; Grégoire et al. 2008). Compared with the 1980s, a significant decrease of this index's values was observed beginning
in the mid-1990s. Canadian landings alone, although not all accounted for, cannot explain the extent of this decrease, which has also occurred when the water in the Gulf of St. Lawrence, i.e. the cold intermediate layer (CIL), has gotten colder (DFO 2008). Demographically, the late 1990s were characterized by the arrival of the strong 1999 year-class. Individuals from this year-class alone accounted for nearly half of the 330,000 t of mackerel landed in Canadian waters between 2000 and 2007. The arrival of this year-class increased the landings in Newfoundland from 2,000 in 2000 to over 40,000 t in 2007 (DFO 2008). Although the 1999 year-class has almost all disappeared, the vast majority of Canadian landings are still from Newfoundland. It is unlikely that this year-class was measured in the egg survey as was done for the strong 1982 year-class, which suggests that most of the fish from this year-class would have used a different spawning site than the traditional site in the southern Gulf.

## Canadian and US Contingents

On the American side, catches from a scientific bottom-trawl survey conducted in the spring were used to calibrate various sequential population analysis models (Overholtz 1991; NEFSC 1996, 2000, 2006). This survey covers the entire U.S. east coast, from Cape Hatteras to Georges Bank. According to the work carried out by Sette (1950) on mackerel distribution and migration in the northwest Atlantic, both contingents could be well covered by this survey.

## Objectives of the Present Study

The primary objective of this study is to determine whether the U.S. spring survey successfully represents the abundance fluctuations of the northern contingent by calculating the proportion of the American abundance index which is located east of the meridian $70^{\circ}$ west, which is west of where Sette (1950, P.270) observed no individuals from the northern contingent. To do this, the aggregated abundance index (number/set) was recalculated by kriging. This approach helped divide the U.S. index into two components located on both sides of the meridian $70^{\circ}$ west.

## MATERIAL AND METHODS

## Data Source

Catch data in numbers and weight (kg) per set from the scientific bottom-trawl survey in spring are from the National Fisheries Science Center (NEFSC) in Woods Hole, MA (Dr. Jon Deroba, NOAA Fisheries, pers. comm.). The other variables associated with these data are: (1) survey name, (2) strata identification, (3) station number, (4) set number, (5) date, (6) time, (7) position (latitude and longitude), (8) depth (m) trawled, and (9) water temperature ( ${ }^{\circ} \mathrm{C}$ ) at the bottom. The numbers and average annual weights per set were calculated from these data by the swept area method and by kriging.

## Data Analysis

## Catch Distribution

For each survey, mackerel catches (number/set) were displayed on maps created with the software Surfer (Golden Software Inc. 2008). Bottom temperatures were interpolated using the same software and the results were superimposed on catch maps. The geographic center of the catches was calculated for each survey using the position of the sets. Geographic centers of all the surveys were presented on the same map in order to compare annual catch concentrations.

## Kriging

Variograms were produced for each survey from the numbers per set and their respective positions. The semivariance calculations were done using the $\mathrm{GS}^{+}$software (Robertson 1998). The choice of a variogram model was based on the coefficient of determination ( $\mathrm{r}^{2}$ ) results (Robertson 1998) and the parameters of the model chosen, on the results of the RSS statistics (residual sum of squares) as calculated by $\mathrm{GS}^{+}$. For a given model, the parameters chosen were those that produced the lowest value of this statistic.

Ordinary point kriging was conducted using the corresponding parameters of the variograms. A correction factor was applied to the variograms that were produced without the occurrence of extreme values. The number of points to include in the search area was set at 16 and no restrictions were applied to the research range. For each survey, point estimates were made to the grid nodes of a 7,247 cell grid measuring $5 \times 5 \mathrm{~km}$ covering the entire area sampled. The new abundance index was defined as the average of all point estimates. This index was compared with the index using the swept area method. Subsequently, averages were calculated for the grid-cells located on either side of the meridian $70^{\circ}$ west to obtain two abundance indices associated with the distribution ranges of both mackerel contingents.

## RESULTS

## Set Characteristics

Between 151 and 251 stations were sampled annually by the scientific bottom-trawl survey (Table 1). The number of stations or sets with mackerel catches ranged between 16 (8.7\%) and 75 (46.9\%) for an annual average (1968-2008) of 44 (25.2\%) stations. To the east of the meridian $70^{\circ}$ west, mackerel were caught at a maximum of 40 ( $25.0 \%$ ) stations in 2001 for an annual average of $11.5(6.6 \%)$ stations. The maximum number of mackerel caught during a set was 15,619 in 1973 for an annual average of 24.4 mackerel per set. The average depths of the sampled stations ranged between 82.8 and 106.3 m and average temperatures at the bottom were between 2.9 and $8.6^{\circ} \mathrm{C}$.

## Catch Distributions

During the period covered by the survey (1968-2008), mackerel were caught over the entire continental shelf as well as at its edge (Figures 1 and 2). However, the catch distribution pattern varied from year to year. For example, for some surveys, catches were concentrated in a given region. With the exception of four years (1999, 2000, 2001 and 2007), very few catches were made east of the meridian $70^{\circ}$ west, i.e. in the region between Cape Cod and Georges Bank. The temperature regime at the bottom has changed dramatically over the years. On some occasions, the highest temperatures were observed only at the edge of the continental shelf, and on other occasions, in the southern portion and/or the median of the sampled area.

## Mean Catch and Weight per Survey

The annual abundance index, expressed as mean numbers per set, reached a minimum value of 0.19 in 1969 and a maximum value of 59.11 in 2001 (Table 2). With the exception of 1968 and 1987, very low values were measured until 1990. The index rose slightly between 1990 and 1996 and following a drop in 1997, it increased again until 2001. Subsequently, changes were observed with values above 25 mackerel per set in 2003, 2004 and 2006. The same annual variations were observed in mean weight per set.

## Kriging

For most surveys, the choice of variogram was based on the spherical model (Table 3). The exponential model was used a few times but no model has helped describe the spatial structure of catches in 1969, 1978, 1980 and 1981 due to an insufficient number of catches. All models selected adjusted well to the semivariance data with coefficients of determination ranging from 0.76 to 1.00 (Table 3).

The annual kriged index reached a low of 0.54 mackerel per set in 1979 and a maximum of 117.45 in 2001 (Table 4). The kriged index, while higher than the swept area index, showed the same annual variations (Figure 3). The relationship between these two indices can be described using a linear regression ( $\mathrm{F}=294.75, \mathrm{r}^{2}=0.89, \mathrm{p}<0.0001$ ) (Figure 4). With the exception of the surveys conducted in 1975, 1997, 1999, 2000 and 2001, all geographic catch centers were found west of $70^{\circ}$ west (Figure 5A).

The annual index associated with the grid-cells of the kriging grid located west of the meridian $70^{\circ}$ west (Figure 5B) ranged between 0.67 (1979) and 119.77 (2004) mackerel per set (Table 4). For the area east of this meridian, the index ranged from 0 (2005) to 217.98 (2001) mackerel per set. The mean numbers per set were generally higher for the region west of the meridian $70^{\circ}$ west. They were higher on the east side in 1999, 2000 and 2001 and slightly higher in 1973, 1975 and 1976, 1985 and 1997 (Figures 6A and 6B).

## DISCUSSION

In the U.S. spring bottom trawl surveys, the most numerous and most significant mackerel catches were generally made west of the meridian $70^{\circ}$ west (Cape Cod). The results from the kriging analyses also show that mackerel were more abundant in this region. Considering, based on observations by Sette (1950), that this meridian is the winter limit separating the two mackerel contingents in the northwest Atlantic, the results presented in this study suggest that the southern contingent, with some exceptions, is more abundant than the northern contingent in the area covered by the survey. However, it is possible that (1) individuals from the northern contingent are found west of the meridian $70^{\circ}$ west, or (2) a portion of the northern contingent winters in Canadian waters and thus remains inaccessible to the U.S. survey. Should this last statement be true, the U.S. index could not be considered representative of the abundance of the two contingents.

The presence of individuals of the northern contingent in the Cape Cod region and in particular west of it is not well documented and most mackerel distribution and migration patterns in Canadian waters have changed significantly over recent years. Most Canadian landings are now in Newfoundland. Fishing in this province, both on the west and east coast, sometimes continues until late October and early November.

Sette mentions two schools of thought regarding mackerel migration (Sette 1950). The first stipulated that mackerel traveled great distances every year between fall fishing sites and wintering sites. The second believed that migrations were much shorter and that mackerel schools, in the fall, headed out to sea to winter in deep waters. Sette (1950) mentioned that it is likely a combination of both. This is probably what occurs in Newfoundland. The deep waters at the edge of the continental shelf, off the Grand Banks of Newfoundland, could serve as wintering areas such as those found off the Scotian Shelf (Grégoire 2006). Mackerel that do not have time to reach this region could be affected by rapid drops in temperature which sometimes
occur in late fall. These falling temperatures could be the reason for the mortalities observed occasionally on the beaches of Newfoundland. The presence of mackerel in winter off the Grand Banks of Newfoundland, and not off the Scotian Shelf and Georges Bank, could explain the almost simultaneous arrival of mackerel on the east and west coasts of Newfoundland (Grégoire et al. 2009). This change in wintering grounds could also be the reason for the substantial drop in commercial catches which has been observed in recent years in Nova Scotia (Grégoire et al. 2009). In addition to this decrease, the bottom trawl surveys conducted in winter on the Scotian Shelf and Georges Bank have yielded very few mackerel, as though they were wintering elsewhere (Grégoire et al. 2009).

The commercial catch pattern in Canadian waters, the very low catches by bottom trawl surveys on the Scotian Shelf and Georges Bank, and the low catches from the U.S. survey in the region between Cape Cod and Georges Bank may be the result of a shift by the Canadian contingent to more northerly regions. This phenomenon was observed recently in Europe (ICES 2008, Jacobsen 2008, Nøttestad 2008).

To ensure proper management of the mackerel fishery, it is essential to improve knowledge about mackerel migration and distribution patterns in the northwest Atlantic. It is also important to consider the role that certain environmental variables could have on recent changes in migration and distribution that have been observed in Canadian waters. A tagging program should also be introduced to study the mixing between the two contingents during the winter fishery in U.S. waters.

## ACKNOWLEDGEMENTS

Very sincere thanks are expressed to Jonathan J. Deroba and Gary Shepherd from the Northeast Fisheries Science Center in Woods Hole for providing us with data from the American abundance survey.

## LEGEND :

$0 \circ 01-50 \bigcirc 50-100 \bigcirc 100-200 \bigcirc$ 200-500 $\bigcirc>500$ number / set

Figure 2. Composite maps of the spatial distribution of Atlantic mackerel (nb/set) for the NEFSC spring research vessels bottom trawl surveys conducted from 1968 to 2008.

Figure 3. Mean number of Atlantic mackerel per set calculated by kriging and from a stratified random design survey for the NEFSC spring research vessels bottom trawl surveys conducted from 1968 to 2008.

Figure 4. Relationship between the mean numbers of Atlantic mackerel per set calculated by kriging and from a stratified random design survey for the NEFSC spring research vessels bottom trawl surveys conducted from 1968 to 2008.

Figure 5. Mean longitude and latitude of Atlantic mackerel catches for each NEFSC spring research vessels bottom trawl survey conducted between 1968 and 2008 (A) and locations of 7,247 meshes used for kriging the numbers per set of Atlantic mackerel (the points are 5 km apart) (B).

Figure 6. Mean number of Atlantic mackerel per set (A) calculated by kriging for the areas located to the west and east of $70^{\circ}$ of longitude W and difference (\%) between the west and east areas (B).

Appendix 1. Mackerel length distributions in May and June for the years 1926 to 1935 and for three categories: southern contingent, mixed and northern contingent (from Sette, 1950).

SETTE'S LENGTH FREQUENCY DATA

Note: Between 1926 and 1932, two different (strong) year-classes characterized the southern and northern contingents. In 1934 and 1935, the southern contingent and mixed distributions were similar.

[^0]:    ${ }^{1}$ Based on all the sets pooled together

[^1]:    ${ }^{1}$ Based on all the sets pooled together

[^2]:    * Spherical $\quad \gamma(\mathrm{h})=\left\{\mathrm{C} 0+\mathrm{C}\left[1.5\left(\frac{\mathrm{~h}}{\mathrm{~A}_{0}}\right)-0.5\left(\frac{\mathrm{~h}}{\mathrm{~A}_{0}}\right)^{3}\right]\right.$ if $\mathrm{h} \leq \mathrm{A}_{0}$, and $\mathrm{C} 0+\mathrm{C}$ otherwise

    Exponential
    $\gamma(h)=C 0+C\left[1-\exp \left(-\frac{h}{A_{0}}\right)\right]$
    ** Residual sum of squares
