#### Abstract

The combined Canada/US Yellowtail Flounder catch in 2013 was 218 mt, with neither country filling its portion of the quota. This is the lowest catch in the time series which began in 1935. Despite the low catch, all three bottom trawl surveys declined to low values relative to their entire time series and catch curve analyses indicate high total mortality rates ( $\mathrm{Z}>1$ ). All three bottom trawl surveys indicate below average recruitment recently. The declining trend in survey biomass in recent years to low levels, despite reductions in catch to low amounts, indicates a poor state of the resource.

This assessment updates the Split Series and Single Series virtual population analysis (VPA) formulations that were approved at the last benchmark model review to estimate stock size and fishing mortality. It aso adds four additional VPAs with M increased to 0.4 for the entire time series and M increased to 0.4 for years 1973 to 2004 and increased to 0.9 or 1.0 for years 2005 onward in response to recommendations made at the 2014 Diagnostic Benchmark. All four constant M VPA formulations exhibit strong retrospective patterns and rho adjustments are recommended for both determining stock status and providing catch advice from these runs, while the increased M since 2005 VPA formulations do not exhibit retrospective patterns. Catches of less than 100 up to 300 mt are required to achieve the TMGC objective of not overfishing, but this advice does not account for the guidance to reduce the fishing mortality rate when stock conditions are poor.

The empirical approach recommended at the 2014 Diagnostic Benchmark was applied. The three recent bottom trawl surveys were scaled to absolute biomass estimates, averaged, and an exploitation rate of $25 \%$ was applied to generate catch advice of 553 mt . This amount of catch is greater than one of the individual surveys. There are also a number of sources of uncertainty which need to be considered, the most important being the exploitation rate to apply.

At the TRAC meeting, the decision was made to no longer use a VPA assessment model to evaluate stock status or provide catch advice. Instead the empirical approach was used to provide catch advice. The exploitation rate recommended for use with the empirical approach was changed from $25 \%$ to a range of $2 \%$ to $16 \%$ to be more consistent with the Eastern Georges Bank cod approach of reducing target $F$ when $M$ increased in recent years. This resulted in 2015 catch advice of 44 mt to 354 mt . Alternatively, a constant quota approach could be used, resulting in 2015 catch advice of 400 mt or less.

## RÉSUMÉ

En 2013, les prises combinées de limande à queue jaune au Canada et aux États-Unis étaient de 218 tm ; aucun des deux pays n'avait atteint sa partie du quota. Il s'agit de la valeur la plus basse de la série chronologique débutant en 1935. Malgré les faibles prises, les trois relevés au chalut de fond ont affiché des valeurs faibles par rapport à l'ensemble de leur série chronologique et des analyses de la courbe des prises indiquent des taux de mortalité totale élevés ( $Z>1$ ). Les trois relevés au chalut de fond indiquent un recrutement inférieur à la moyenne récemment. La tendance à la baisse dans la biomasse d'après les relevés des dernières années vers de faibles niveaux, et ce, malgré les réductions des prises à de faibles quantités, indique un mauvais état de la ressource.

La présente évaluation apporte une mise à jour aux formules d'analyses de populations virtuelles (APV) à série fractionnée et à série unique qui ont été approuvées au dernier examen du modèle de référence et qui servent à estimer la taille du stock et le taux de mortalité des poissons. Elle ajoute également quatre autres APV avec une augmentation de la mortalité naturelle à 0,4 pour l'ensemble de la série chronologique, une augmentation de la mortalité naturelle à 0,4 pour les années 1973 à 2004 et une augmentation à 0,9 ou à 1,0 à partir des années 2005 en réponse aux recommandations faites lors de l'analyse comparative des diagnostics en 2014. Les quatre formules d'analyse de population virtuelle en ce qui a trait à la mortalité affichent de fortes tendances rétrospectives et des corrections rho sont recommandées pour déterminer l'état du stock et pour fournir des recommandations de prises à partir de ces analyses, alors que l'augmentation de la mortalité depuis les formules d'analyse de population virtuelle de 2005 ne présente pas de tendances rétrospectives. Des prises de moins de 100 tm à 300 tm sont nécessaires pour atteindre l'objectif du Comité d'orientation de la gestion des stocks transfrontaliers (COGST) de ne pas faire de surpêche, mais cette recommandation ne tient pas compte de l'orientation visant à réduire le taux de mortalité par pêche lorsque les conditions des stocks sont faibles.
L'approche empirique recommandée à l'analyse comparative des diagnostics de 2014 a été appliquée. Les trois récents relevés au chalut de fond ont été adaptés pour les estimations de la biomasse absolue et mis en moyenne, et un taux d'exploitation de $25 \%$ a été appliqué afin de produire des recommandations de prises de 553 tm . Ce nombre de prises est supérieur à celui d'un des relevés individuels. Il existe également un certain nombre de sources d'incertitude qui doivent être prises en compte, la plus importante étant le taux d'exploitation à appliquer.
À la réunion du Comité d'évaluation des ressources transfrontalières (CERT), la décision a été prise de ne plus utiliser le modèle d'évaluation fondé sur l'analyse de population virtuelle pour évaluer l'état du stock ou fournir des recommandations de prises. Au lieu, l'approche empirique a été utilisée pour fournir des recommandations de prises. Le taux d'exploitation recommandé pour l'approche empirique est passé de $25 \%$ à une fourchette de $2 \%$ à $16 \%$, pour être plus conforme à l'approche utilisée pour la morue de l'est du banc de Georges visant à réduire le taux cible de mortalité par pêche (F) lorsque le taux de mortalité naturelle (M) a augmenté au cours des dernières années. Cela a donné lieu à une recommandation de prises de 44 tm à 354 tm en 2015. Par ailleurs, il est possible d'utiliser une approche constante selon les quotas, ce qui a donné lieu à une recommandation de prises de 400 tm ou moins en 2015.

## INTRODUCTION

The Georges Bank Yellowtail Flounder (Limanda ferruginea) stock is a transboundary resource in Canadian and US jurisdictions. This paper updates the last stock assessment of Yellowtail Flounder on Georges Bank, completed by Canada and the US (Legault et al. 2013), taking into account advice from the 2005 benchmark review (Gavaris et al. 2005) and the 2014 Diagnostic Benchmark (O'Brien and Clark 2014). A primary objective of both benchmark reviews was to address the retrospective pattern that had been apparent from assessments conducted during the past several years. During the 2005 benchmark assessment meeting, several analytical models were reviewed, all of which indicated that the fishery catch at age and survey abundance at age show differences that cannot be reconciled. Various possible reasons for the retrospective pattern were identified including an increase in natural mortality, large amounts of unreported catch, and changes in survey catchability since 1995. The consensus view from the 2005 benchmark meeting was that management advice should be formulated on the basis of results from several approaches:

- Analysis of data from survey and fishery (trends in relative fishing mortality (F) and total mortality (Z))
- Base Case Virtual Population Analysis (VPA) model formulation from the 2004 assessment
- Two new VPA model formulations with minor and major changes to Base Case

The analytical methods used in the current assessment are based on revised model formulations adopted during the 2005 Transboundary Resources Assessment Committee (TRAC) benchmark review using updated information from both countries on catches and survey indices of abundance. During the 2009 TRAC meeting, it was decided that neither the Base Case nor Minor Change VPA would be considered any longer because neither had been used for management advice in a number of years (O'Brien and Worcester 2009). The Major Change model will be referred to as the "Split Series" model in this document since it is now the default model, while the Base Case model will be referred to as the "Single Series" model.

The 2014 Diagnostic Benchmark recommended an empirical approach to providing catch advice based on the three bottom trawl surveys and an assumed exploitation rate. This benchmark also recommended increasing the natural mortality rate from 0.2 to 0.4 and consideration of additional increase in recent years due to possible lethal effects of Ichthyophonus sp. (a parasitic protozoan). Another recommendation from this benchmark was to use surveys for partial areas of Georges Bank as a test of the VPA results for the entire Georges Bank. If the VPA biomass estimates for the whole bank are less than the biomass estimates from a partial area then this can be used to reject the VPA if uncertainty in both estimates is considered. The 2014 Diagnostic Benchmark was a large undertaking with 46 working papers with 105 authors ( 56 unique) from 10 institutions totaling just over 1,000 pages.
Last year, the Split Series VPA model was used as the basis of status determination. This model downweighted the Canadian 2008 and 2009 surveys in the tuning process to account for their higher uncertainty caused by single large catches of Yellowtail Flounder in those years. This formulation indicated that catches have not reduced fishing mortality ( $F$ ) below $F_{\text {ref }}$ and have not had the expected effect on adult (age 3+) biomass or spawning stock biomass. If the 2014 catch quota had been set based on this model, this pattern of failing to achieve management objectives was expected to continue given the model's retrospective pattern. The TRAC recommended not basing 2014 catches on these unadjusted model projection results. Instead, both the Split Series and Single Series models had their population abundance at the start of 2013 reduced based on the Mohn's rho for spawning stock biomass. These projections had much lower catch advice in 2014 compared to the unadjusted projections. Based on examination of these two analyses, the TRAC concluded that to achieve a high probability that $F$
in 2014 will be less than Fref, a 2014 quota of less than 200 mt would be required. In order to achieve high probability that adult biomass will increase from 2014 to 2015, a 2014 quota of less than 500 mt would be required. Due to the assumption used for the 2012 year class in the projections, the increase in adult biomass will be optimistic if the 2012 year class is as poor as the recent year classes. The TRAC concluded that catches well below 500 mt are likely needed to achieve the harvest strategy. The Transboundary Management Guidance Committee (TMGC) negotiated the combined US-Canada catch quota for 2014 to be 400 mt .

Yellowtail Flounder range from southern Labrador to Chesapeake Bay and are typically caught at depths between 30 and 70 m . A major concentration occurs on Georges Bank from the Northeast Peak to the east of the Great South Channel. Yellowtail Flounder have previously been described as relatively sedentary. However, there are also studies that counter this classification with off bottom movements (Walsh and Morgan 2004; Cadrin and Westwood 2004), limited seasonal movements (Royce et al. 1959; Lux 1963; Stone and Nelson 2003), and transboundary movements both east and west across the Hague Line (Stone and Nelson 2003; Cadrin 2005). On Georges Bank, spawning occurs during late spring and summer, peaking in May. Eggs are deposited on or near the bottom and, after fertilization, float to the surface where they drift during development. Larvae are pelagic for a month or more; then they become demersal and settle to benthic habitats. Based on the distribution of both ichthyoplankton and mature adults, spawning occurs on both sides of the Hague Line. Growth is sexually dimorphic, with females growing at a faster rate than males (Lux and Nichy 1969; Moseley 1986; Cadrin 2003). Yellowtail Flounder maturation occurs earlier than in most flatfish with approximately half of females mature at age 2 and nearly all females mature at age 3 .

## MANAGEMENT

Historical and new information pertaining to the current management unit for the Georges Bank Yellowtail Flounder stock was reviewed during the 2005 and 2014 benchmark assessments. Tagging data, larval distribution, vital population parameters (i.e. growth, survival, recruitment, reproduction, abundance), and geographic patterns of landings and survey data indicate that Georges Bank Yellowtail Flounder comprise a relatively discrete stock, separate from those on the western Scotian Shelf, off Cape Cod, and in southern New England waters (Royce et al. 1959; Lux 1963; Neilson et al. 1986; Begg et al. 1999; Cadrin 2003; Stone and Nelson 2003). Based on information from comprehensive reviews by Cadrin (2003; 2010) and recent results from cooperative science/industry tagging programs conducted by Canada and the US, there does not appear to be any justification for redefining the geographic boundaries of the Georges Bank Yellowtail Flounder stock management unit.
The management unit currently recognized by Canada and the US for the transboundary Georges Bank stock includes the entire bank east of the Great South Channel to the Northeast Peak, encompassing Canadian fisheries statistical areas 5Zj, 5Zm, 5Zn and 5Zh (Figure 1a) and US statistical reporting areas 522, 525, 551, 552, 561 and 562 (Figure 1b). Both Canada and the US employ the same management unit.
In 1984, the International Court of Justice (ICJ) determined US and Canadian jurisdictions for Georges Bank fishery resources (ICJ 1984). At that time, there was no Canadian fishery for Yellowtail Flounder. When a Canadian fishery developed in the early 1990s, Canada and US were exchanging information but conducting separate assessments. In the late 1990s, joint assessments were developed, and in 2001 a sharing agreement was formed (TMGC 2002). Since the establishment of the US and Canada sharing agreement in 2001, advice for the Georges Bank Yellowtail Flounder relied primarily on a bilateral management system provided by the TMGC. The agreement includes TAC for each country based on a formulaic calculation using both historical catch and current spatial stock distribution as determined by the three
bottom trawl surveys. The quota sharing agreement between the two countries requires that catches from all sources be counted against the national allocations, regardless of whether the catch was landed or discarded. When accounting for catch, the assumption has always been made that all discarded fish die. Recent field work has demonstrated high discard mortality rates for Yellowtail Flounder (Barkley and Cadrin 2012), supporting this assumption. Although there is coordination between the US and Canadian fishery management, objectives between the two countries remain inconsistent, with US law requiring stock biomass rebuilding targets that are not part of Canadian management. The passage of the International Fisheries Clarification Act in 2010 (Shark and Fishery Conservation Act 2011) relaxed the US rebuilding requirements, allowing more consistent management between the two countries.

## THE FISHERIES

Exploitation of the Georges Bank Yellowtail Flounder stock began in the mid-1930s by the US trawler fleet. Landings (including discards) increased from 400 mt in 1935 to 9,800 mt in 1949, then decreased in the early 1950s to $2,200 \mathrm{mt}$ in 1956, and increased again in the late 1950s (Table 1 and Figure 2). The highest annual catches occurred during 1963-1976 (average: $17,500 \mathrm{mt}$ ) and included modest catches by distant water fleets (Table 1 and Figure 2). No catches of Yellowtail Flounder by nations other than Canada and US have occurred since 1975. In 2001, the decision was made to manage the stock as a transboundary resource in Canadian and US jurisdictions (TMGC 2002). Catches averaged around 3,500 mt between 1985 and 1994, and then dropped to a low of $1,135 \mathrm{mt}$ in 1995 when fishing effort was markedly reduced in order to allow the stock to rebuild. The US fishery in the management area has been constrained by spatial expansion of Closed Area II in 1994 (Figure 1b) and by extension to yearround closure in December 1994, as well as mesh size and gear regulations and limits on days fished. In 2004, a Yellowtail Flounder Special Access Program (SAP) in Closed Area II allowed the US bottom trawl fishery short-term access to the area for the first time since 1995. This SAP did not continue in subsequent years. In 2010, a Haddock SAP in Closed Area II allowed the US bottom trawl fishery short-term access to the area and some Yellowtail Flounder were caught as bycatch in this fishery. A directed Canadian fishery began on eastern Georges Bank in 1993, pursued mainly by small otter trawlers (<20 m). Catches by both nations (including discards) steadily increased (with increasing quotas) from a low of 1,135 mt in 1995, when the stock was considered to be in a collapsed state, to $7,419 \mathrm{mt}$ in 2001. Since 2004, decreasing quotas and an inability of Canadian fishermen to fill their portion of the quota have resulted in a declining trend in catches through 2013 (catch in $2013=218 \mathrm{mt}$, the lowest value in the time series 19352013).

## UNITED STATES

The main fishing gear used in the US fishery to catch Yellowtail Flounder is the otter trawl, accounting for more than $95 \%$ of the total US landings in recent years, although scallop dredges have accounted for some historical landings. US trawlers that land Yellowtail Flounder generally target multiple species on the southwest part of the bank, and on the northern edge along the western and southern boundaries of Closed Area II. Recreational fishing for Yellowtail Flounder is negligible.

Landings of Yellowtail Flounder from Georges Bank by the US fishery during 1994-2013 were derived from the trip-based allocation described in the GARM III Data meeting (GARM 2007; Legault et al. 2008b; Palmer 2008; Wigley et al. 2007a). US landings have been limited by quotas in recent years. Total US Yellowtail Flounder landings (excluding discards) for the 2013 fishery were 130 mt , a 71\% decrease from 2012 (Table 1 and Figure 2).

US discarded catch for years 1994-2013 was estimated using the Standardized Bycatch Reporting Methodology (SBRM) recommended in the GARM III Data meeting (GARM 2007, Wigley et al. 2007b). Observed ratios of discards of Yellowtail Flounder to kept of all species for large mesh otter trawl, small mesh otter trawl, and scallop dredge were applied to the total landings by these gears and by half-year. Large and small mesh otter trawl gears were separated at 5.5 inch ( 14 cm ) cod-end mesh size. The large mesh fishery mainly targets groundfish, monkfish, skates, dogfish, and fluke (summer flounder), while the small mesh fishery mainly targets whiting (silver hake), herring, mackerel, and squid. Uncertainty in the discard estimates was estimated based on the SBRM approach detailed in the GARM III Data meeting (GARM 2007; Wigley et al. 2007b). Average annual US discards were approximately 20\% of the US catch in years 1994-2013 (Table 1 and Figure 2). Total discards of Yellowtail Flounder in the US decreased 74\% from 2012 (188 mt) to 2013 ( 49 mt ). All three gears exhibited decreases in discards with relatively small coefficients of variation (Table 2).

The total US catch of Georges Bank Yellowtail Flounder in 2013, including discards, was 179 mt . This value can be compared to the quota monitoring estimated catch of 187 mt for calendar year 2013, data kindly provided by Dan Caless of the Greater Atlantic Regional Fisheries Office (Table 3). The strong similarity from the two estimates both this year and last year is encouraging, as this has not always been the case in the past.

The US Georges Bank Yellowtail Flounder quota for fishing year 2012 (1 May 2012 to 30 April 2013) was set at 215 mt . Monitoring of the US catches relative to the quota was based on Vessel Monitoring Systems (VMS) and a call-in system for both landings and discards.
Reporting on the Regional Office webpage
(http://www.nero.noaa.gov/ro/fso/MultiMonReports.htm) indicates the US groundfish fishery caught $35.6 \%$ of its sub-quota ( 55 mt ) for the 2013 fishing year and the scallop fleet caught $90 \%$ of its sub-quota ( 42 mt ) for the 2013 fishing year. The overall US catch from all fleets was $47 \%$ of the US quota for fishing year 2013.

## CANADA

Canadian fishermen initiated a directed fishery for Yellowtail Flounder on Georges Bank in 1993. Prior to 1993, Canadian landings were low, typically less than 100 mt (Table 1 and Figure 2). Landings of $2,139 \mathrm{mt}$ of Yellowtail Flounder occurred in 1994, when the fishery was unrestricted. After a TAC of 400 mt was established, Yellowtail Flounder landings dropped to 464 mt in 1995. Subsequently, both quotas and landings increased and in 2001 landings reached a peak at $2,913 \mathrm{mt}$. The majority of Canadian landings of Yellowtail Flounder were made by otter trawl from vessels less than 20 m (tonnage classes 1-3). The fishery generally occurred from June to December, with most landings in the third quarter. Since 2004, with the exception of 2011 and 2012, there has been no directed Canadian Yellowtail Flounder fishery; the Canadian quota has been reserved to cover bycatch in the commercial groundfish and scallop fisheries. In 2011 and 2012, a directed fishery was permitted from June 1 to December 31. Landings have been less than 100 mt every year since 2004, with a low of <1 mt in 2013. From 2004-2011 and in 2013, most of the reported Yellowtail Flounder landings were from trips directed for Haddock. In 2012, there were 9 trips directed for Yellowtail Flounder that caught most of the landed Yellowtail Flounder.

The Canadian offshore scallop fishery is the source of Canadian Yellowtail Flounder discards on Georges Bank. As a result of the 2005 benchmark review, these data are now incorporated into the Canadian fishery catch and catch at age for 1973 onward (Gavaris et al. 2005). Discards are not recorded in the Canadian fishery statistics and are therefore estimated from at-sea observer deployments using the methodology documented in Van Eeckhaute et al. (2005). Since August 2004, there has been routine observer coverage on vessels in the Canadian scallop fishery on Georges Bank (Table 4). Discards for the years 2004-2013 were obtained by estimating a
monthly prorated discard rate (kg/(hr*meters)), using a 3-month moving-average calculation to account for the seasonal pattern in bycatch rate, applied to a monthly standardized effort (Tables 5-6) (Van Eeckhaute et al. 2010). This approach resulted in slightly different discard estimates for years 2005-2012 than the previously presented values based on a kg/hr effort metric. The result of these calculations for 2013 is a discard estimate of 39 mt , the lowest in the time series (Table 1 and Figure 2).

For 2013, the total Canadian catch, including discards, was 39 mt , a 57\% decrease from 2012, which is $14 \%$ of the 2013 TAC of 285 mt .

## LENGTH AND AGE COMPOSITION

The level of US port sampling continued to be strong in 2013, with 2,138 length measurements available from 30 samples, resulting in 1,650 lengths/100 mt of landings (Table 7). This level of sampling has generally resulted in increased precision (i.e. low coefficients of variation) for the US landings at age from 1994-2013, as estimated by a bootstrapping procedure (Table 8). The port samples also provided 607 age measurements for use in age-length keys. The Northeast Fisheries Observer Program provided an additional 1,382 length measurements of discarded fish from 318 trips, which were used to characterize the size composition of the US discards.

The US landings are classified by market category (large, small, medium, and unclassified) and this categorization is used to determine the size and age distributions. Both the amount and the proportion of Yellowtail Flounder landed in the large market category have generally increased since 1995 (from approximately 50\% to approximately 75\%). Examination of the size distributions of the large and small market categories continues to show some overlap in the 3638 cm range, but overall discrimination between the groups was apparent (Figure 3).

In 2013, no samples were collected from the $<1 \mathrm{mt}$ of Canadian landings (Table 7). The Canadian landings at age were assumed to follow the same proportions at age as the US landings and to have the same weights at age as the US landings.
The US discard length frequencies were generated from observer data, expanded to the total weight of discards by gear type and half year. Large mesh trawl discards showed a strong peak near the minimum allowed size (Figure 4). Small mesh discards accounted for only a small portion of the total discards and had few fish measured for length, resulting in a disjointed distribution of fish at length (Figure 4). The small mesh otter trawl fishery is prohibited from landing groundfish, resulting in discarded fish above the minimum size regulation. Scallop dredge discards were mainly legal-sized fish, as has been typically seen for dredge gear in the past (Figure 4).
The size composition of Yellowtail Flounder discards in the Canadian offshore scallop fishery was estimated by half year using length measurements obtained from 17 observed trips in 2013. These length measurements were prorated to the annual total estimated bycatch at size using the corresponding half year length-weight relationship and half year bycatch (mt) estimates using the methods of Stone and Gavaris (2005).
A comparison of the 2013 size composition of Yellowtail Flounder catch by country shows identical length distributions for landings by the US and Canada, due to the reason described above (Figure 5). US discards were slightly larger in mean size but similar in spread of the distributions relative to Canadian discards (Figure 6). The total catch was also shifted towards larger fish for the US than Canada, although the low magnitude of Canadian catch relative to US catch makes this comparison suspect (Figure 7).
Although otoliths are used to determine ages for Grand Bank Yellowtail Flounder (Walsh and Burnett 2001), age determination of Georges Bank Yellowtail Flounder using otoliths is hampered by the presence of weak, diffuse, or split opaque zones and strong checks, which
can make interpretation of annuli subjective and difficult (Stone and Perley 2002). Therefore, scales are the preferred structure for aging Georges Bank Yellowtail Flounder. Percent agreement on scale ages by the US readers continues to be high (>85\% for most studies) with no indication of bias (http://www.nefsc.noaa.gov/fbp/QA-QC/yt-results.html).
For the US fishery, sample length frequencies were expanded to total landings at size using the ratio of landings to sample weight (predicted from length-weight relationships by season; Lux 1969), and apportioned to age using pooled-sex age-length keys by half year groups. Landings were converted by market category and half year, while discards were converted by gear and half-year. The age-length keys for the US landings used only age samples from US port samples. In the past, the age-length keys for the US discards used age samples from at-sea observers of the discarded catch supplemented with US surveys. Since 2004, the scales collected by the observers have not been aged, so the US surveys and commercial landings provided ages for US discards.

No scale samples were available for the Canadian fishery in 2013. Therefore, the Canadian discards at length were converted to catch at age using the US age-length keys by half-year and catch type (landings vs discards). Canadian landings and discards accounted for $0.2 \%$ and $18 \%$ of the total 2013 catch respectively.

In 2013, ages 4 and 5 (2009 and 2008 year-classes, respectively) dominated US landings, while ages 2-4 dominated US and Canadian discards, with only minor contribution from Canadian landings (Figure 8). Since the mid-1990s, ages 2-4 have constituted most of the exploited population, with very low catches of age 1 fish due to the implementation of larger mesh (increased from 5.5 to 6 inches in May 1994) in the cod-end of US commercial trawl gear (Table 9 and Figure 9a-b). Despite management measures intended to reduce fishing effort over the past several years, there are few fish older than age 5 in the catch at age.

The fishery mean weights at age for Canadian and US landings and discards were derived using the applicable age-length keys, length frequencies, and length-weight relationships. The mean weight at age ( kg ) for the Canadian and US landings were quite similar and generally were more variable at older ages (5+) during the mid-1980s to the mid-1990s. The combined fishery weights at age were calculated from Canadian and US landings and discards, weighting by the respective catch at age (Table 10 and Figure 10). Weights at age have been increasing recently, following a decline during the mid-2000s, and are returning to levels seen in the late 1970s/early 1980s. Recent weights at age (WAA) values are above average for age 1 and below average for the other ages, but all ages are within the range of past WAA calculations since 1973.

## ABUNDANCE INDICES

Research bottom trawl surveys are conducted annually on Georges Bank by the Canadian Department of Fisheries and Oceans (DFO) in February (denoted spring) and by the US National Marine Fisheries Service (NMFS) Northeast Fisheries Science Center (NEFSC) in April (denoted spring) and October (denoted fall). Both agencies use a stratified random design, although different strata boundaries are used by the two countries (Figure 11).
The NMFS spring and fall bottom trawl survey catches (strata 13-21), NMFS scallop survey catches (scallop strata $54,55,58-72,74$ ), and DFO spring bottom trawl survey catches (strata 5Z1-5Z4) were used to estimate relative stock biomass and relative abundance at age for Georges Bank Yellowtail Flounder. Conversion coefficients, which adjust for survey door, vessel, and net changes in NMFS groundfish surveys (1.22 for BMV oval doors, 0.85 for the former NOAA ship Delaware II relative to the former NOAA ship Albatross IV, and 1.76 for the

Yankee 41 net; Rago et al. 1994; Byrne and Forrester 1991) were applied to the catch of each tow for years 1973-2008.

Beginning in 2009, the NMFS bottom trawl surveys were conducted with a new vessel, the NOAA ship Henry B. Bigelow, which uses a different net and protocols from the previous survey vessel. Conversion coefficients by length have been estimated for Yellowtail Flounder (Brooks et al. 2010; Table 11) and were applied in this assessment.

Given the calibration at length for the US spring and fall surveys, the question was raised during a previous TRAC meeting whether there were indications of recruiting year-classes in the uncalibrated Henry B. Bigelow data that were removed by the calibration to Albatross IV units. The raw length distributions from the Henry B. Bigelow were plotted together with the calibrated length distributions in Albatross IV units and no indication of strong year-classes at small lengths ( $<30 \mathrm{~cm}$ ) were observed in any of the recent US spring or fall surveys (Figure 12).

Based on the recommendation of the 2014 Diagnostic Benchmark (O'Brien and Clark 2014), the annual catch per tow for each of the three bottom trawl surveys were converted to absolute abundance estimates. These calculations start by using the door width for each net to compute the area trawled by a single tow in each survey (Table 12). The mean catch per tow is then expanded to a minimum swept area amount by multiplying by the ratio of the total area to the area swept by a single tow. A literature estimate of the catchability of the gear, meaning the number of Yellowtail Flounder in the path of the tow which were caught, is used to expand the minimum swept area amount to total abundance. This literature value for catchability was derived in working paper 13 of the 2014 Diagnostic Benchmark as the mean of the value 0.22 in Harden Jones et al. (1977) and four values of $0.33,0.42,0.43$, and 0.45 in Somerton et al. (2007). The Harden Jones et al. (1977) study was conducted with English plaice in the North Sea using a Granton otter trawl and the Somerton et al. (2007) study was conducted with four flatfish species (arrowtooth flounder, flathead sole, rex sole, and Dover sole) in the Gulf of Alaska using a Poly nor'eastern survey trawl. For ease of comparison with the VPA estimates, the total abundance values from the DFO and US bottom trawl surveys are divided by 1,000 . Thus, catch per tow in numbers of fish and kg multiplied by the conversion factor 566.527 (DFO) or 1311.655 (US spring and fall in Albatross IV units) results in estimated abundance in thousands of fish and metric tons (Table 12).
Trends in Yellowtail Flounder biomass indices from the four surveys track each other quite well over the past two decades, with the exception of the DFO survey in 2008 and 2009, which were influenced by single large tows (Figure 13a-f). The minimum swept area biomass estimated from the DFO survey increased from 1995 to 2001, declined through 2004, fluctuated through 2007, and then increased dramatically in 2008 and 2009 due to single large tows in each year, as seen by the unusually large coefficients of variation for those years (Table 13 and Figure 13e-f). Exclusion of these single tows resulted in a decline in the indices by about an order of magnitude, as shown in previous assessments (Legault et al. 2009, 2010, 2011). The 2014 DFO biomass is the second smallest in the time series. The NMFS spring series was high in the mid-1970s, low in the late 1980s through mid-1990s, high from 1999 through 2003, increased moderately from 2004 through 2012, and decreased in both 2013 and 2014 (Table 14 and Figure 13b,c,f). The NMFS fall survey, which is the longest time series, was high in the mid1960s through mid-1970s, low in the mid-1980s through mid-1990s, increased through 2001, declined through 2005, and has remained at levels comparable to the late 1960s for years 2007-2009, but in 2010 through 2012 declined to the values comparable to the early 1980s and further declined in 2013 (Table 15 and Figure 13b,d,f). The scallop survey stratified mean catch per tow shows a strong increase from low levels in the mid-1990s to a peak in 1998 followed by a decline through 2005, and has fluctuated since in years when the entire bank was surveyed (Table 16 and Figure13b). Both the NMFS spring and fall survey indices show high inter-annual variability during the periods of high abundance (i.e. the 1960s and 1970s), which may reflect
the patchy distribution of Yellowtail Flounder on Georges Bank. The coefficients of variation of the three groundfish surveys are generally comparable, with the exception of the unusually large values for the DFO survey in 2008 and 2009 due to the single large tows each year (Tables 1316 and Figure 13e).

The spatial distribution of catches (weight/tow) for the most recent year compared with the previous ten year average for the three groundfish surveys show that Yellowtail Flounder distribution on Georges Bank in the most recent year has been consistent relative to the previous ten years (Figure 14a-b). Note the 2009 through 2014 NEFSC survey values were adjusted from Henry B. Bigelow to Albatross IV equivalents by dividing Henry B. Bigelow catch in weight by 2.244 (spring) or 2.402 (fall). Since 1996, most of the DFO survey biomass and abundance of Yellowtail Flounder has occurred in strata $5 Z 2$ and $5 Z 4$ (Figure 15a). However, in 2008 and 2009 almost the entire Canadian survey catch occurred in just one or two tows in stratum 5Z1, making interpretation of trends over time difficult. The NEFSC bottom trawl surveys have been dominated by stratum 16 since the mid-1990s (Figure 15b-c).

Age-structured indices of abundance for NMFS spring and fall surveys were derived using survey specific age-length keys. Prior to 2004, age-length keys from NMFS spring surveys had been substituted to derive age composition for same-year DFO spring surveys, as no ages were available from the DFO surveys because of difficulties associated with age interpretation from otoliths (Stone and Perley 2002). To avoid having to use substituted age data, NMFS personnel have been ageing scales collected on DFO surveys since 2004 and continued to do so this year.

There is some indication of cohort tracking in all three of the bottom trawl surveys (Figure 16am ). Even though each index is noisy, the age specific trends track relatively well among the four surveys (Tables 13-16 and Figure 17a-b).

Measurements of individual Yellowtail Flounder length and weight were collected from the US spring and fall surveys to examine whether changes in condition have occurred over time (Figure 18a-b). Median weights at length from both surveys indicate a declining trend for Yellowtail Flounder $33-44 \mathrm{~cm}$, sizes associated with the majority of commercial catch, although the most recent years indicate a return towards the mean. The condition factor (Fulton's K) for male and female Yellowtail Flounder in the DFO survey shows more of a continued decline (Figure 18c).
Trends in relative fishing mortality and total mortality from the surveys were examined as part of the 2005 assessment benchmark formulations. Relative fishing mortality (fishery catch biomass/survey biomass, scaled to the mean for 1987-2007) was quite variable but followed a similar trend for all four surveys, with a sharp decline to low levels since 1995 (Figure 19). In contrast, estimates of total mortality rates from the surveys for ages 2,3 and $4-6$, although noisy, were without trend and indicate no overall reduction in mortality since 1995 (Figure 20). Similarly, time series of cohort Z estimated from the three bottom trawl surveys do not indicate a reduction in recent years (Figure 21a-c). This disparity in the basic data continues to cause difficulty for the stock assessment of Georges Bank Yellowtail Flounder.

## EMPIRICAL APPROACH

The 2014 Diagnostic Benchmark recommended an empirical approach be considered for catch advice (O'Brien and Clark 2014). The three bottom trawl surveys are used to create a modelfree estimate of population abundance that can either be compared with the catch to create an exploitation rate or have an exploitation rate applied to create catch advice. The Henry B. Bigelow data are used directly in these calculations to avoid the complexities that arise due to calibration with the Albatross IV. The stratified mean catch per tow in weight is expanded to total
biomass based on the ratio of the total area surveyed to the area of a single trawl. Due to the different footprint of the Henry B. Bigelow relative to the Albatross $I V$, the estimated biomass values for the NEFSC spring and fall surveys differ from the values presented earlier for the Albatross IV converted time series (Table 17). This minimum swept area biomass is divided by the catchability of 0.37 to create an estimate of the biomass. The survey biomass estimates from DFO and the NEFSC spring survey in year $t$ and the NEFSC fall survey in year $\mathrm{t}-1$ are averaged to form the estimate of population biomass in year $t$. Multiplying the mean biomass by an exploitation rate of 0.25 results in the catch advice for year $\mathrm{t}+1$ (Table 17).
This approach to providing catch advice can result in some odd situations. For example, for both 2013 and 2014 the DFO estimate of population biomass is less than the catch advice derived from the average biomass in those years (Table 17). The empirical approach also ignores the uncertainty in both the catch/tow values and the catchability value used to expand the minimum swept area population estimate to a population estimate. The uncertainty in the surveys can be approximated quickly from the coefficient of variation associated with each annual survey (provided in the earlier survey tables). Random draws from each of the surveys given the point estimate, the CV, and an assumption of normal distributions can be averaged over the three surveys to create a distribution of population biomass. Applying the constant exploitation rate to the distribution of population biomass, results in a distribution of catch advice in each year. These distributions are summarized according to some common percentiles (Table 18). Alternatively, the point estimates for annual catch per tow can be converted to a distribution of annual population abundances by dividing each value by a beta distribution for the catchability of the surveys. Application of the constant exploitation rate again results in a distribution of catch advice (Table 18). This beta distribution was formed using the method of moments given a mean value of 0.37 and CV of 0.26 , based on the decision made at the Diagnostic Benchmark meeting. Finally, both sources of uncertainty can be included in the distribution of population abundance and multiplied by the constant exploitation rate to provide distributions of catch advice (Table 18). As can be seen by comparing the resulting catch advice distributions, the uncertainty in survey catchability causes greater variability in the catch advice than the uncertainty in the surveys. Using both sources of uncertainty increases the amount of uncertainty in the catch advice. This uncertainty should be considered if this approach is used to provide catch advice.
One additional source of uncertainty in the empirical approach is the exploitation rate to apply. Since the exploitation rate is a direct multiplier of the population biomass to generate the catch advice, the catch advice will change linearly with changes in the exploitation rate. Halving or doubling the exploitation rate will result in halving or doubling the catch advice. The exploitation rate of 0.25 was derived from equilibrium per recruit calculations under the assumption that the natural mortality rate in recent years was greater than the new value of 0.4 . This assumption was based on a mass balance equation, which demonstrated that given the estimated catch and survey values, an additional source of mortality must be occurring to account for the continued decline of the population. Equilibrium exploitation rate, defined as the ratio of yield per recruit to total biomass per recruit, ranged between 0.24 and 0.27 at $F_{0.1}$ and between 0.22 and 0.24 at $F_{40 \%}$ for $M$ between 0.4 and 1.1. This approach assumes that the target $F$ increases when $M$ increases within the time series of the assessment, counter to the approach recommended for Eastern Georges Bank cod, which recommends a decrease in the target $F$ when $M$ increases within the time series of an assessment. For example, using the results from last year's Split Series assessment and the same definition of exploitation rate (ypr/tsb), but holding the target fishing mortality rate at 0.52 (the estimate of $\mathrm{F}_{40 \% \mathrm{MsP}}$ using those data) results in target exploitation rates decreasing from 0.20 to 0.07 when M increases from 0.4 to 1.1. The EGB cod approach of decreasing the $F$ target when $M$ increases within the assessment time series would result in even lower exploitation rates as $M$ increases within the assessment time series (ypr/tsb).

## ESTIMATION OF STOCK PARAMETERS

Results from assessment analyses conducted in recent years have displayed: a) retrospective patterns; b) residual patterns that are indicative of a discontinuity starting in 1995; and c) fishing mortality rates that are not consistent with the decline in abundance along cohorts evident in the survey data. Essentially, the catch at age data and assumed natural mortality rate cannot be reconciled with the change in survey abundance indices from ages 2 and 3 to ages 4 and older.
The empirical evidence suggests that significant modifications to the population and fishery dynamics assumptions are required to reconcile the fishery and the survey observations. Models that adopt such modifications imply major consequences on underlying processes or fishery monitoring procedures. The magnitude of implied changes to natural mortality rate, survey catchability relationships, or unreported catch is so great that the acceptability of models that incorporate these effects is suspect. However, these models may provide better catch advice for management of this resource than ignoring the changes in underlying processes (ICES 2008).

In view of these reservations, adoption of a benchmark formulation that incorporated these modifications to assumptions as the sole basis for management advice was not advocated (Gavaris et al. 2005). Therefore, the TRAC recommended that management advice be formulated after considering the results from three VPA approaches: Base Case (now called Single Series), Minor Change, and Major Change (now called Split Series). The Minor Change VPA was never used in any subsequent assessment (Stone and Legault 2005; Legault et al. 2006, 2007, 2008a) and it was agreed during the 2009 TRAC that it would not be continued in the future (Legault et al. 2009). The Single Series VPA was continued for a number of years after the benchmark, but was not used to provide management advice for five years (Legault et al. 2006, 2007, 2008a, 2009, 2010). At the 2011 TRAC meeting, the re-emergence of a retrospective pattern in the Split Series VPA model led to the re-evaluation of the Single Series VPA model. The Single Series VPA continued to show a stronger retrospective pattern than the Split Series VPA, but some TRAC participants considered it better to use just a single retrospective adjustment (the Mohn's rho adjustment to starting population abundance for projections) rather than two (splitting the surveys and applying a retrospective adjustment). At the 2012 TRAC, the Split Series VPA with retrospective adjustment, the Single Series VPA with retrospective adjustment, and three alternative retrospective "fixes" were used to provide catch advice (Legault et al. 2012). This large number of models caused concern and led to a Term of Reference at the Eastern Georges Bank cod benchmark assessment meeting to review criteria for evaluation and modification of benchmark assessments. Based on these discussions, only the Split Series VPA with retrospective adjustment and Single Series VPA with retrospective adjustments were provided for recommending catch advice in 2013 (Legault et al. 2013). As mentioned above, the 2014 Diagnostic Benchmark recommended a change in the natural mortality rate from 0.2 to 0.4 . The $\mathrm{M}=0.2$ results are shown for comparison with previous years, while the $\mathrm{M}=0.4$ results are now considered the best estimates. There is a possibility that M has increased even more in recent years. See Table 19 for a summary of changes to the VPA formulations since the 2005 assessment benchmark noting the TRAC decision to not use the VPA model for the 2014 assessment.

The VPA is calibrated using the adaptive framework ADAPT (Conser and Powers 1990; Gavaris 1988; Parrack 1986) to calibrate the sequential population analysis with the research survey abundance trend results, specifically the NOAA Fisheries Toolbox VPA v3.4. The model formulation employed assumed error in the catch at age was negligible. Errors in the abundance indices were assumed independent and identically distributed after taking natural logarithms of the values. The exception to this assumption is the DFO survey values for 2008 and 2009 were downweighted (residuals multiplied by 0.5 ) to reflect the higher uncertainty associated with these observations relative to all other survey observations. Zero observations for abundance
indices were treated as missing data because the logarithm of zero is undefined. The annual natural mortality rate, M , was assumed constant and equal to either 0.2 or 0.4 for all ages and years, or else increase from 0.4 to either 0.9 or 1.0 in 2005 (see below). The fishing mortality rates for age groups 4, 5 and $6+$ were assumed equal. These model assumptions and methods were the same as those applied in the last assessment, with the exception of the change in the natural mortality rate (Legault et al. 2013). Both point estimates and bootstrap statistics of the estimated parameters were derived using only the US software for this assessment.

The Split Series VPA recommended during the benchmark assessment expanded the ages from 6+ to 12, assumed a constant small number of fish (1000) survived to the start of age 13, allowed power relationships between indices and population abundance for younger ages (1-3), and split the survey time series between 1994 and 1995. This model could not be fit well in previous assessments (Legault et al. 2006, 2007, 2008a) due to a lack of catch at older ages creating bimodal bootstrap distributions. Following the precedent of previous assessments, the Split Series VPA was reformulated to be the same as the Single Series VPA (i.e. by reverting to ages 1-6+ for the catch at age), with the exception that the survey time series were split at 1995 (Legault et al. 2006, 2007, 2008a, 2009, 2010, 2011, 2012, 2013). This means that indices and population abundance are assumed linearly related at all ages and that a 6+ group is used for all fish aged 6 and older in the population dynamics equations. Splitting the survey series had been sufficient to remove the retrospective pattern and the pattern in residuals until the 2011 assessment, and was recommended for management advice because it more closely followed the pattern observed in the indices.

The Split Series VPA used updated annual catch at age (including US and Canadian discards), $C_{a, t}$, for ages $a=1$ to $6+$, and time $t=1973$ to 2013, where $t$ represents the beginning of the time interval during which the catch was taken. The VPA was calibrated to bottom trawl survey indices, $I_{s, a, t}$, for:
$s_{1}=$ DFO spring, ages $a=2$ to $6+$, time $t=1987$ to 1994
$s_{2}=$ DFO spring, ages $a=2$ to $6+$, time $t=1995$ to 2014
(note: $s_{2}=$ DFO spring, ages $a=2$ to $6+$, time $t=2008$ to 2009 residuals were downweighted)
$s_{3}=$ NMFS spring (Yankee 41), ages $a=1$ to $6+$, time $t=1973$ to 1981
$s_{4}=$ NMFS spring (Yankee 36), ages $a=1$ to 6+, time $t=1982$ to 1994
$s_{5}=$ NMFS spring (Yankee 36), ages $a=1$ to 6+, time $t=1995$ to 2014
(note: $s_{5}=$ NMFS spring (Yankee 36), ages $a=1$ to $6+$, time $t=2009$-2014 were converted from Henry B. Bigelow to Albatross IV equivalent)
$s_{6}=$ NMFS fall, ages $a=1$ to $6+$, time $t=1973.5$ to 1994.5
$s_{7}=$ NMFS fall, ages $a=1$ to $6+$, time $t=1995.5$ to 2013.5
(note: $s_{7}=$ NMFS fall, ages $a=1$ to $6+$, time $t=2009.5-2013.5$ were converted from Henry $B$. Bigelow to Albatross IV equivalent)
$s_{8}=$ NMFS scallop, age $a=1$, time $t=1982.5$ to 1994.5
$s_{9}=$ NMFS scallop, age $a=1$, time $t=1995.5$ to 2013.5
(note: the NMFS scallop survey was not used for years 1986, 1989, 1999, 2000, 2008, 2011, 2012, or 2013)

Splitting the survey time series between 1994 and 1995 could not be justified based on changes in the survey design or implementation. Rather the split is considered to alias unknown mechanisms causing the retrospective pattern in the Single Series VPA. Population abundance
at age 1 in the terminal year plus one (2014) was assumed equal to the geometric mean over the most recent 10 years (2004-2013). Population abundance in the terminal year plus one (2014) was estimated directly for ages 2-5.

## BUILDING THE BRIDGE

There were two changes to the data from the 2013 TRAC assessment. The Canadian discards at age were revised for 2005 through 2012. These were small changes resulting in changes to the total catch at age of $<2 \%$ for all ages and changes to the total weights at age of $<1 \%$. Small changes (2-4\%) in the 2009-2011 US surveys were found as well. These two small data changes were evaluated relative to the final 2013 TRAC assessment and had only a minor impact on results (trend lines not noticeably different from 2013 TRAC for F, SSB, or recruitment; Figure 22).

These revised catch and survey data were the starting point for the new assessment, which then added a year of catch and survey indices.

## DIAGNOSTICS

As expected, both the Split Series and Single Series VPA with M=0.2 and M=0.4 (four combinations) resulted in strong retrospective patterns (described in detail below). Evidence was presented at the Diagnostic Benchmark that the natural mortality rate had increased in recent years. Coincidentally, an increase in recent $M$ could address the retrospective pattern. Thus, for the recommended value of $M=0.4$, a search was conducted for a recent $M$ (years 2005 to present) that would remove the retrospective pattern for the two VPA formulations. The recent value of $M$ needed to remove the retrospective patterns in F and SSB were 0.9 and 1.0 for the Split Series and Single Series VPAs, respectively (Figure 23a-b). Results for all six combinations (Split Series vs Single Series and M=0.2 vs 0.4 vs 0.4 with recent increase) are presented below to allow comparisons among the model formulations and account for the recommendations from the 2005 Assessment Benchmark and the 2014 Diagnostic Benchmark.
The six VPAs performed similarly compared to previous assessments in terms of relative error and bias in the population abundance estimates with lower relative error and bias at older ages than at younger ages (Table 20a-f). This pattern of higher uncertainty in the younger ages has been seen in previous assessments and is due to having less information about these cohorts. The magnitude of relative error and relative bias at age was similar among the six VPAs despite changes in the estimated population abundances (Table 20a-f).
Survey catchability constants (q) for the three Split Series VPAs also followed similar patterns to previous assessments (Table 20a-c and Figure 24a-c). The most notable pattern was the increase in estimated values at nearly all ages between the pre-1995 and the recent period (1995 to present). There have been no changes in the survey design or operations that can explain such changes. These changes in $q$ are considered to be aliasing unknown mechanisms for the sole purpose of producing a better fitting model. Management strategy evaluations have demonstrated that even if the true source of the retrospective pattern is misreported catch or changes in natural mortality, this approach of splitting the time series to address the retrospective problem produces better performance (true F closer to target F, and thus better catch advice) than ignoring the retrospective pattern (ICES 2008). This pattern remains in the Split Series M0409 VPA despite the recent years not exhibiting a retrospective pattern because there is still a change in the data between 1994 and 1995 that caused the Split Series VPA to first be used. The survey catchability constants (q) for the three Single Series VPAs follow similar patterns over ages to the Split Series VPAs, but at a magnitude between the early and recent $q$ values of the Split Series VPAs (Table 20d-f and Figure 24d-f).

Patterning in the residuals of all six VPAs can be observed with mainly positive or negative residuals during different periods throughout the time series (Figure 25a-f). Generally the Split Series are better than the Single Series, with little differences between the M=0.2 and M=0.4 VPAs, but the cases with an increased $M$ in recent years produced better diagnostics than the constant M formulations.

Retrospective analysis for the four constant M VPAs indicate a strong tendency to overestimate spawning stock biomass and recruitment and underestimate $F$, relative to the terminal year (Table 21a-b and Figure 26a-I). These retrospective patterns are stronger than observed in the Base Case formulations of previous assessments (Legault et al. 2009, 2010, 2011, 2012, 2013). The two VPAs with increased M since 2005 result in no retrospective pattern due to the method used to select the value of M for the recent years.

During the 2014 Diagnostic Benchmark, the TRAC agreed that the empirical estimates of biomass from surveys not included in the VPA due to only partial coverage of Georges Bank should be used to inform and evaluate consistency of VPA biomass estimates. Model results well below the absolute estimates can be used to reject model results, but only when uncertainty in both estimates indicates a real difference. There were six working papers presented at the Diagnostic Benchmark meeting that provided biomass estimates from surveys not included in the VPA. Comparison of these estimates with the six VPAs shows that the Split Series M02, Split Series M04, and Single Series M02 VPAs have SSB and mean biomass estimates below at least one of the independent surveys (Figure 27a,b,d). The Single Series M04 VPA and the two VPAs with increased M since 2005 pass this test (Figure 27c,e,f).

Based on historical precedence, the Split Series VPA with either M=0.2 or M=0.4 and a retrospective adjustment is recommended as the basis for estimating current stock size and fishing mortality rate. However, both these models failed the evaluation relative to independent surveys. Based on previous TRAC and NEFMC SSC advice, none of the four constant M VPAs without a retrospective adjustment should be used for estimating current stock size or providing catch advice due to their large retrospective patterns. This leaves the Single Series M04 VPA with rho adjustment and the two VPAs with increased M since 2005 as possible models for estimating current stock size and fishing mortality rate. However, the Single Series M04 VPA has a very strong retrospective pattern and the Split Series M0409 and Single Series M0410 have unexplained recruitment trends. Furthermore, the use of either VPA with increased $M$ in recent years for stock status requires the determination of an appropriate fishing mortality reference value. Thus, there is no clear choice for providing stock status. Instead, general statements will be made comparing the results from the six VPAs.

## STOCK STATUS

Population abundance at age for the start of the year was estimated for years 1973-2014 (Table 22a-f) along with estimates of fishing mortality rates at age during years 1973-2013 (Table 23a-f). Due to the backward convergence of VPA, the Split and Single Series VPAs with the same M have identical estimates for early years, diverging since around 2000. The fishery weights at age, assumed to represent mid-year weights, were used to derive beginning of year weights at age (Table 24), and these were used to calculate beginning of year population biomass (Table 25a-b). In the US, spawning stock biomass is the legal status determination criterion and is computed assuming maturity at age and the proportion of mortality within a year that occurs prior to spawning ( $p=0.4167$ ).
Adult population biomass (Jan-1, ages 3+) increased from a low in 1995 to a relative peak in 2003 according to all six VPAs (Table 25a-b and Figures 28a-f, 29a-b). The differences in estimated adult biomass during the period 1973 through 2003 are due to the two different M values assumed during this time period, with the higher estimates associated with $\mathrm{M}=0.4$ and
the lower estimates associated with $\mathrm{M}=0.2$. Adult biomass estimated by the four constant M VPAs declined to low values in 2006 and then either continued a slight decline in the $\mathrm{M}=0.2$ VPAs or else increased in the M=0.4 VPAs. Note that all four constant M VPAs have strong retrospective patterns that result in rho adjusted estimates of adult biomass in 2014 at the lowest values in their time series (Table 26). The two VPAs with increased M since 2005 had a second peak in adult biomass in 2008 then decreased to low values in 2014. Spawning stock biomass for the six VPAs followed similar patterns as adult biomass (Tables 25a-b, 26 and Figure 30a-b).

Age 1 recruitment estimated by the four constant M VPAs has been much lower in recent years than in previous years, while age 1 recruitment estimated by the two VPAs with increased M since 2005 estimate that the highest recruitment occurred during 2005 and 2006 (Table 22a-f and Figure 31a-b). The high recruitments in the early 2000s estimated by the two VPAs with increased M since 2005 are simply a reflection that many more age 1 fish are needed to account for the observed catch when M is 0.9 or 1.0 than when M is 0.4 . Recruitment signals of this magnitude were not observed in any of the surveys. The low recent recruitment limits the ability of the stock to produce yield or rebuild. Note the opposite pattern in the retrospective pattern for the two VPAs with increased M since 2005 relative to the four constant M VPAs (Figure 31b).

Fishing mortality for fully recruited ages 4+ was close to or above 1.0 between 1973 and 1995, fluctuated between 0.36 and 0.97 during 1996-2003, increased in 2004, and then declined to a low value in 2013 in all six VPAs (Table 23a-f and Figure 32a-b). The strong retrospective patterns in the four constant $M$ VPAs results in the rho adjusted $F$ values being above the current reference point of $F_{\text {ref }}=0.25$, although this reference point may not be appropriate for VPAs that use an M value different than 0.2 (Table 27 and see Fishery Reference Points section below).

Total population biomass (age 1+) has generally tracked the three groundfish surveys, although splitting the series between 1994 and 1995 implies high catchability of the surveys in recent years (Table 25a-b and Figure 33a-c).
The bootstrap uncertainty estimates do not capture the full amount of uncertainty in this assessment due to the strong retrospective patterns in the four constant M VPA results and the large sudden change in $M$ in the two VPAs with increased $M$ since 2005. A retrospective adjustment has been recommended in the past by TRAC for catch advice to account for this additional uncertainty. The retrospective adjustment is computed as $1 /(1+r h o)$ and is multiplied by the point estimate to create the rho adjusted values. Application of this rho adjustment to terminal year estimates from the six VPAs show how large these changes are for the constant M VPAs and how small the rho adjustments are for the two VPAs with increased M since 2005 (Table 26 and Figure 34).

## FISHERY REFERENCE POINTS

## PER RECRUIT REFERENCE POINTS

The current reference fishing mortality rate used by the TMGC ( $F_{\text {ref }}=0.25$, ages $4+$ ) was derived from both $F_{0.1}$ and $F_{40 \% M S P}$ calculations, which were numerically equal in value when the $F_{\text {ref }}$ value was selected (TMGC 2003). Both the 2002 and 2008 assessment yield per recruit analysis (NEFSC 2002, 2008) confirmed that both these values remain at 0.25 . This is the same value as the $\mathrm{F}_{\text {MSY }}$ proxy of $\mathrm{F}_{40 \% \mathrm{MSP}}$ used for US management (NEFSC 2008). The current three year averages for weights at age and fishery partial recruitment produce estimates for both $\mathrm{F}_{40 \% \mathrm{MSP}}$ and $\mathrm{F}_{0.1}$ of 0.28-0.30 for the two $\mathrm{M}=0.2 \mathrm{VPAs}$, but much larger values for the other four VPAs (Tables 27-28). As mentioned above, if the natural mortality rate used in the VPA is
changed from 0.2 , then the $F_{\text {ref }}$ value should be changed. If $M$ is constant at 0.4 , then $F_{\text {ref }}$ of $0.60-0.77$ would result from $\mathrm{F}_{40 \% \mathrm{MSP}}$ or $\mathrm{F}_{0.1}$. If M increases within the time series, then TRAC will need to provide guidance on the scientific information needed to negotiate a new $\mathrm{F}_{\text {ref }}$.

## STOCK AND RECRUITMENT

The TMGC does not have an explicit biomass target. There is evidence of reduced recruitment at low levels (below approximately $5,000 \mathrm{mt}$ ) of spawning stock biomass (Figures 35a-c and 36a-f). In the US, a similar stock-recruitment relationship from the GARM III assessment (NEFSC 2008) was used to estimate the SSB $_{\text {MSY }}$ proxy by projecting the population for many years with $\mathrm{F}=\mathrm{F}_{40 \% \mathrm{MSP}}$ and recruitment randomly selecting from the cumulative distribution function of recruitment observed at $S S B>5,000 \mathrm{mt}$. The SSB $_{\text {MSY }}$ level of $43,200 \mathrm{mt}$ of spawning stock biomass was set as the rebuilding goal in the US for this stock (NEFSC 2008). Spawning stock biomass is currently well below the US rebuilding goal (rho adjusted $\mathrm{SSB}_{2013} / \mathrm{SSB}_{\text {MSY }}<6 \%$ for all six VPAs).

Rebuilding projections are required in the US when stocks are overfished (defined as SSB $<1 / 2$ SSB $_{\text {Msץ }}$ ). The rebuilding target for Georges Bank Yellowtail Flounder is a spawning stock biomass of $43,200 \mathrm{mt}$ (denoted SSB msy ). This value was set during GARM III (NEFSC 2008) based on using $\mathrm{F}_{40 \% \mathrm{MSP}}$ as a proxy for $\mathrm{F}_{\mathrm{MSY}}$ and conducting stochastic projections fishing at this rate for 100 years. The median SSB at the end of these 100 year projections was set as the SSB $_{\text {MSY }}$ proxy. These projections depend on weights at age, fishery partial recruitment, maturity at age, natural mortality at age, and recruitment assumptions. If any of these data are changed, the resulting SSB $_{\text {MSY }}$ proxy will change; however, these changes are typically assumed to be minor and the accepted value (currently $43,200 \mathrm{mt}$ ) is kept as the rebuilding target. This is obviously not the case for four of the VPAs, so new estimates of SSB $_{\text {MSY }}$ will be required if any of these four VPAs are selected for providing catch advice. The original rebuilding target year was 2014. However, the International Fisheries Clarification Act allowed extension of the rebuilding time. The New England Fisheries Management Council has set the new rebuilding end date as 2032. This is so far into the future that no rebuilding projections were considered. As the rebuilding date gets closer, the biomass reference point for this stock should be reevaluated in light of current fishery, biological, and environmental conditions.

## OUTLOOK

This outlook is provided in terms of consequences with respect to the harvest reference points for alternative catch quotas in 2015. Uncertainty about current biomass generates uncertainty in forecast results, which is expressed here as the risk of exceeding $F_{\text {ref }}=0.25$. The risk calculations assist in evaluating the consequences of alternative catch quotas by providing a general measure of the uncertainties. However, they are dependent on the data and model assumptions and do not include uncertainty due to variations in weight at age, partial recruitment to the fishery, natural mortality, systematic errors in data reporting, or the possibility that the model may not reflect stock dynamics closely enough.
Projections for all six VPAs were made using 2011-2013 average fishery partial recruitment and fishery weights at age to account for the most recent conditions in the fishery and biological characteristics (Table 28). Deterministic projections were made for all six VPAs with and without rho adjustment for comparative purposes (Table 29a-I). Following previous practice, the rho adjusted 2014 Jan-1 population abundance at age values used the SSB rho value for all ages. All the projections assume a catch in 2014 equal to the 400 mt total quota and apply $\mathrm{F}_{\text {ref }}=0.25$ in 2015. This catch results in wide range of fully selected fishing mortality rates for the twelve projections ranging from 0.09 to 1.82 . Fishing at $F_{\text {ref }}$ in 2015 allows the adult (ages $3+$ ) Jan-1 biomass to increase in all twelve projections, but this is due to the large cohort age 1 in 2014.

This dependence of an increased biomass from year two to year three in the projection has been documented in the past two assessments (Legault et al. 2012, 2013) and is not demonstrated again in this assessment. The fishery yield in 2015 ranges from 49 to 333 mt for the six rho adjusted projections, which contrasts with the range of 224 to $1,063 \mathrm{mt}$ for the six unadjusted projections. The TRAC has recommended not using unadjusted projections in cases when strong retrospective patterns are present. These deterministic projections are provided to allow tracking of cohort effects and comparison of proportional impacts by age in each year of the projections.
The TRAC uses stochastic projections to examine the risk of overfishing, meaning exceeding $F_{\text {ref, }}$ in 2015 and the probability of stock increase, meaning the change in adult (ages 3+) Jan-1 biomass from 2015 to 2016, resulting from given quotas being set in 2015. These stochastic projections use bootstrapped realizations of the 2014 population abundance at age to characterize the uncertainty of starting conditions and randomly draw from a two stage cumulative distribution function of recruitment estimates as described above in the Stock and Recruitment section. However, there is essentially no impact of the recruitment assumption at age 1 in year 2015 or 2016 on the TRAC risk of overfishing or change in adult biomass, as can be seen by tracking these cohorts in the deterministic projection tables. All other aspects of the stochastic projections are the same as the deterministic projections described above. The changes between deterministic and stochastic projections, when F in 2015 is set to 0.25 , are minor, as can be observed by comparing Table 29a-I with Table 30.

The stochastic projection results for the four unadjusted constant M VPA projections are shown in Tables 29-32 for completeness only. They are shown in Tables 30-32 using a different font to reflect the recommendation from previous TRAC meetings to not use these projections for catch advice due to strong retrospective patterns. The remaining eight projections require a 2015 catch of between <100 mt and 300 mt to have a neutral risk of exceeding $\mathrm{F}_{\text {ref }}$ (Table 31a-c and Figure $37 a-b$ ), similar to the catch advice from last year. As noted above, $\mathrm{F}_{\text {ref }}$ may not be appropriate for many of the projections. For demonstration purposes the probability that 2015 F is greater than or equal to 0.6 (a possible $\mathrm{F}_{\text {ref }}$ when $\mathrm{M}=0.4$ ) was computed for all twelve projections (Table 32). As noted above in the deterministic projections, the adult biomass is expected to increase from 2015 to 2016 due to the use of the geometric mean recruitment for the 2014 age 1 value almost regardless of the fishing mortality rate in 2015. Thus, the metric of adult biomass increase from 2015 to 2016 is not informative from these projections. The risk of overfishing increases rapidly with small changes in the 2015 quota, so catches associated with $25 \%$ and $75 \%$ risk of overfishing are not presented (Figure 37a-b). The change in adult biomass from 2015 to 2016 is close to a linear function of the 2015 catch, but almost all projections resulting in increased biomass due to the large value assumed for the 2014 age 1 cohort (Figure 38a-b). The change in probability of biomass increase (or a $10 \%$ increase) from one to zero occurs over a relatively small range of 2015 catch for some of the rho adjusted projections (Figure 39a-b).
Age structure, fish growth, and spatial distribution reflect stock productivity. As discussed in detail at the 2014 Diagnostic Benchmark, the interpretation of the current age structure depends on the natural mortality rate assumed in equilibrium calculations. When M is 0.2 , the current age structure appears to be highly truncated, while when M is 0.4 the current age structure appears only slightly truncated on a proportion basis, and when M is 0.9 or 1.0 the current age structure appears good on a proportional basis (Figure 40a-f). However, the age structure in 2013 relative to the average of 1973 through 2012 shows large reductions in absolute numbers of fish at young ages in all six scenarios. Growth has been variable without strong trends, but condition factor has declined over the last decade. Spatial distribution patterns from the three groundfish surveys generally follow historical averages. Truncated age structure (at older, younger, or all
ages) and reduced but improving condition factor indicate current resource productivity is lower than historical levels.

## MANAGEMENT CONSIDERATIONS

Although the Split Series VPA has been used previously for management decisions, the mechanisms for the large changes in survey catchability are not easily explained. These changes in survey catchability are most appropriately thought of as aliasing an unknown mechanism that produces a better fitting model. The inability to plausibly explain these survey catchability changes causes increased uncertainty in this assessment relative to other assessments. Although the intention of the Split Series VPA was to eliminate the retrospective pattern, the pattern has re-emerged. Consideration of a number of alternative "fixes" to the retrospective pattern in 2012 indicated that the catch advice was robust to how these inconsistencies in the data were treated and gave support to the management advice for this stock (Legault et al. 2012).

Consistent management by Canada and the US is required to ensure that conservation objectives are not compromised.

The change from previous assessments can be seen by examining the historical retrospective analysis, which plots the results from previous assessments instead of peeling back years from the current assessment (Figure 41). The historical retrospective analysis incorporates all data and model formulation changes as well as the number of years in the assessment. The change in the strength of the 2005 year-class (shown at age 1 in 2006 in the recruitment panel) contributes to the change in estimated spawning stock biomass, similar to the assessment retrospective analysis. However, the retrospective pattern is continuing, despite the reduction in the strength of the 2005 year-class in the last three assessments. So there is more than just a missed year-class that is generating the retrospective pattern.
The performance of the catch advice provided historically for this stock can be examined by comparing the expectation when the advice was provided with estimates for fishing mortality rates and biomass from the 2012 assessment. These comparisons were kindly provided by Tom Nies (New England Fishery Management Council) and are shown in the Appendix. This table was not updated this year due to the multiple VPAs considered. The results demonstrate the impact of the retrospective pattern. Catch advice was provided that was expected to cause a fishing mortality rate of $F_{\text {ref }}$ or lower. The actual catch was usually less than the quota, yet the current assessment estimates a fishing mortality rate much higher than $F_{\text {ref. }}$. This is due to the directional bias of the retrospective pattern. Since the biomass was estimated too high, the catch advice was set too high. Once the biomass is estimated at a lower amount, then that same catch has an associated fishing mortality rate well above the one originally used to set the catch advice. Changes in weight at age, partial recruitment to the fishery, and recruitment can also impact the accuracy of the projections. The past performance of catch advice should be considered when setting future catch quotas.
An additional perspective on the past performance of catch advice can be made by comparing the catch at age in weight for 2013 projected from previous assessments with the observed values measured for 2013 (Figure 42). The three projections from the 2012 and 2013 TRAC meetings are from the Split Series model. The current estimate is simply the catch at age in numbers multiplied by the catch weight at age. The 2012 and 2013 projections without retrospective adjustments shows more catch at old ages both in absolute and relative terms than the actual 2013 catch observed in this assessment. In contrast, the 2012 rho adjusted projections are close in magnitude to the actual catch, although even these projections have proportionally too many old fish in the catch. This difference between projected and observed
age structure is due to whatever mechanism is causing the retrospective pattern and lies at the heart of the difficulties faced by this assessment.

## TRAC MEETING ANALYSES AND DECISIONS

The TRAC met 23-26 June 2014 in Woods Hole, MA to review the Georges Bank Yellowtail Flounder stock assessment and conduct other business. A major decision from this meeting was to not use any VPA formulation to provide stock status or catch advice. This decision was based on the poor performance of all six VPA formulations. The two $\mathrm{M}=0.2$ formulations were not considered appropriate due to the decision made during the 2014 Diagnostic Benchmark (O'Brien and Clark 2014) that 0.4 was a better value for natural mortality of Yellowtail Flounder. These formulations had been provided simply as a link to previous assessments. The two $\mathrm{M}=0.4$ for all years formulations had retrospective patterns that were too strong, did not provide biomass estimates greater than all the partial survey estimates (a diagnostic recommended during the 2014 Diagnostic Benchmark), and had large trends in the residual patterns. The remaining two formulations which increased the natural mortality rate since 2005 had estimates of recruitment in the mid 2000s which were not reflected in any surveys. Furthermore, there was no evidence to support such large increases in the natural mortality rate. The increases in M were determined by a procedure that examined a range of values and selected the one that removed the retrospective pattern in SSB and F. This was not considered to be an appropriate manner to determine such an important biological parameter because many other choices for the year for the increase, whether to increase immediately in one year or more gradually, which ages change $M$, etc. could also result in removing the retrospective pattern, and there is no objective way to choose among these many possible retrospective "fixes." Thus, the TRAC by consensus agreed that no VPA formulation would be used to estimate historical patterns of exploitation or abundance. This means the TRAC cannot provide advice on stock status, examine model diagnostics, or conduct projections for catch advice. No VPA analyses will be considered during the next TRAC meeting.
The TRAC decided to provide catch advice based on an empirical approach defined during the 2014 Diagnostic Benchmark (O'Brien and Clark, 2014) and described above. During the meeting, an inconsistency was noted between how the target fishing mortality rate was determined for Eastern Georges Bank (EGB) cod and Georges Bank Yellowtail Flounder. Specifically, when the natural mortality rate for EGB cod increased from 0.2 to 0.8 within the time series of the assessment, the target fishing mortality rate decreased from 0.18 to 0.11 . In contrast, the empirical approach for Georges Bank Yellowtail Flounder calculated the target exploitation rate by considering a range of natural mortality rates greater than the base value of 0.4 (up to 1.1) but for each $M$ value computed new values of $F_{40 \%}$ and $F_{0.1}$, both of which increased substantially as M increased. Thus, in one case (cod) target $F$ decreased when M increased and in the other case (Yellowtail Flounder) target $F$ increased when $M$ increased. This inconsistency was discussed and it was agreed that the cod approach of decreasing the target $F$ when $M$ increased was more appropriate. However, specific advice regarding the value of $M$ and how much to decrease the target F for Yellowtail Flounder was not provided.

During the presentation of the Georges Bank Yellowtail Flounder assessment at the TRAC meeting, a table was shown demonstrating a lack of stability in the exploitation rate (defined as yield per recruit divided by total stock biomass per recruit) over a range of $M$ values with associated $\mathrm{F}_{40 \%}$ and $\mathrm{F}_{0.1}$ values (slide 57 in the presentation). After the TRAC meeting, this table was discovered to be in error, the denominator for the exploitation rate was incorrectly referenced in the calculations. The original and corrected values for the exploitation rate and resulting 2015 catch advice are provided in Table 33. The original (incorrect) values were used to claim the exploitation rate under either F40\% or F0.1 was not as stable as originally claimed during the Diagnostic Benchmark. This claim is not true; the exploitation rate is stable for values
of M between 0.4 and 1.1, just at a slightly lower level than estimated during the Diagnostic Benchmark (approximately 22\% instead of 25\%) due to slight changes in selectivity and weights at age. This stability in exploitation rate is a result of increasing F as M increases (see the second column in Table 33).
At the TRAC meeting, results from a yield per recruit analysis were shown on screen to examine the relationship between the exploitation rate and combinations of the natural and fishing mortality rates. These calculations used the recent weights at age and maturity at age data available as well as estimates of the fishery selectivity at age from the Split Series M=0.4 VPA. The results demonstrated that many combinations of M and F could produce a given exploitation rate and that for a given value of $F$, increasing $M$ from 0.4 to 1.1 often led to large decreases in the exploitation rate. After examining a number of combinations of M and F , the TRAC decided to include a short table in the TRAC Status Report showing a range of exploitation rates from $2 \%$ to $16 \%$ as the best estimates of the target exploitation rate that should be used in the empirical approach. Application of these exploitation rates result in 2015 catch advice of 44 mt to 354 mt .

Another way of examining the relationships among $M, F$, and exploitation rate is to make a contour plot showing isopleths of equal exploitation rates based on the information examined during the TRAC meeting. Neither of the following two contour plots was generated or examined during the TRAC meeting. The $F_{40 \%}$ and $F_{0.1}$ values for a number of $M$ values are shown in the first contour plot to demonstrate the large increases in these values when $M$ increases, while the exploitation rate remains relatively constant (Figure 43). However, as discussed above, this approach contradicts the decision made for EGB cod to reduce $F$ when $M$ increases within an assessment time period. Holding the target $F$ constant or reducing it as $M$ increases leads to large decreases in the exploitation rate (Figure 44). Also shown in this contour plot for demonstration purposes is a polygon of potential exploitation rates. This polygon was defined by setting the left boundary to 0.6 because the mass balance equation indicated $M$ has increased above the 0.4 base value. The right boundary is simply the largest $M$ value explored (1.1). The top boundary is defined by a target $F$ of 0.65 , which is an approximate mean from the $F_{40 \%}=0.7$ and $F_{0.1}=0.6$ values associated with the Split Series $M=0.4$ yield per recruit analysis (Table 27). The lower bound of the polygon is defined by assuming the same rate of reduction in target $F$ with an increase in M as was used in the EGB cod stock assessment. This polygon encompasses exploitation rates of approximately $6 \%$ to $16 \%$ and shows how increasing the assumed value of M leads to generally lower exploitation rates. For example, when M is 0.8 the exploitation rates are approximately $11 \%$ to $12 \%$ while when M is 1.0 the exploitation rates are approximately $7 \%$ to $9 \%$. Also shown in the plot is a line of constant total mortality equal to 1.05 (derived from the base $M$ of 0.4 and associated target $F$ of 0.65 ). If the goal is to maintain the total mortality rate at 1.05 , then reductions in $F$ cause large reductions in the exploitation rate as $M$ increases. Since a specific value of $M$ was not recommended by the TRAC for recent years when it is assumed to have increased, consideration of a range of possible $M$ values can be used in negotiations of the exploitation rate to be applied (since $F_{\text {ref }}$ is no longer applicable). The TMGC harvest strategy to reduce $F$ when the stock is in poor condition should additionally be considered during these negotiations.

An alternative approach to management that could be considered is to use a constant quota. The TRAC recommended a constant quota of 400 mt or less based on not increasing the quota relative to the 2014 quota due to concerns about stock declines and comparisons to output from the constant exploitation rate.

Whether a constant exploitation rate or a constant quota approach is selected by TMGC, the TRAC recommends using a specific approach for at least three years to evaluate the ability of the stock to respond in the short term. Recently catches have been well below quotas, yet the stock has continued to decline.

Table 11. Length based calibration factors for Yellowtail Flounder (see Brooks et al. 2010 for details of derivation). Numbers at length from Henry B. Bigelow tows should be divided by the calibration factor in the corresponding length bin. It is recommended that these calibration factors be applied with all 6 digits to the right of the decimal point.

| Length | Calibration |
| :---: | ---: |
| $\leq 18$ | 3.857302 |
| 19 | 3.857302 |
| 20 | 3.857302 |
| 21 | 3.621597 |
| 22 | 3.385892 |
| 23 | 3.150187 |
| 24 | 2.914482 |
| 25 | 2.678777 |
| 26 | 2.443072 |
| 27 | 2.207367 |
| 28 | 1.971662 |
| 29 | 1.971657 |
| $\geq 30$ | 1.971657 |

Table 12. Derivation of conversion factors relating catch per tow in numbers of fish and kg to abundance estimates in thousands of fish and metric tons. See text for details.

|  | DFO | US Spring <br> and Fall |
| ---: | ---: | ---: |
| Total Area in Set $=$ | 7421 | 10871 |
| Area Swept by Tow $=$ | 0.035403 | 0.0224 |
| Catchability $=$ | 0.37 | 0.37 |
| Units in VPA $=$ | 1000 | 1000 |
| Conversion Factor $=$ | 566.527 | 1311.655 |

Table 30. Projection results under two fishing mortality rates: $F_{\text {ref }}=0.25$ and $75 \% F_{\text {ref }}=0.1875$. The rows definitions are Catch=median Catch ( $m t$ ) in 2015, Adult Jan-1 $B=$ median beginning year age 3+ biomass in 2015, SSB=spawning stock biomass in 2015, delta $B=$ change in median adult Jan-1 biomass from 2015 to 2016, P(B inc) = probability that adult Jan-1 biomass will increase from 2015 to 2016, P(B inc $10 \%)$ = probability that adult Jan-1 biomass will increase by at least $10 \%$ from 2015 to 2016. Results shown in a light gray font indicate that they do not sufficiently address the retrospective problem.

Figure 6. Comparison of US and Canadian discards at length for Georges Bank Yellowtail Flounder.

## US-Canadian Yellowtail Flounder Catch, 2013

Figure 7. Comparison of US and Canadian catch (landings plus discards) at length for Georges Bank Yellowtail Flounder.

2013

Figure 8. Catch at age of Georges Bank Yellowtail Flounder from the four components of Canadian and US landings and discards.

## Catch at Age

Figure 9a. Catch at age for Georges Bank Yellowtail Flounder, Canadian and US fisheries combined. (The area of the bubble is proportional to the magnitude of the catch). Diagonal red lines denote the 1975, 1985, 1995, and 2005 year-classes.

## Catch Proportions at Age

Figure 9b. Proportions of catch at age for Georges Bank Yellowtail Flounder, Canadian and US fisheries combined. (The area of the bubble is proportional to the magnitude of the proportion). Diagonal red lines denote the 1975, 1985, 1995, and 2005 year-classes.

Figure 10. Trends in mean weight at age from the Georges Bank Yellowtail Flounder fishery (Canada and US combined, including discards). Dashed lines denote average of time series.

Figure 11. DFO (top) and NMFS (bottom) strata used to derive research survey abundance indices for Georges Bank groundfish surveys. Note NMFS stratum 22 is not used in assessment.

Figure 11. (Continued.) NMFS scallop survey strata used to derive research survey abundance indices for Georges Bank groundfish surveys. Strata 54, 55, 58-72, and 74 are used to estimate the abundance of Yellowtail Flounder for this assessment.

Figure 12. Catch per tow in numbers of fish for the US spring and fall surveys by the Henry B. Bigelow. The lines denote the original observations and the dots the calibrated values converted to Albatross IV units. The calibration is calculated using the curve in the lower right panel (Calibrated = Original/Calibration Coefficient).

Figure 13a. Four survey biomass indices (DFO, NEFSC spring, NEFSC fall and NEFSC scallop) for Yellowtail Flounder on Georges Bank rescaled to their respective means for years 1987-2007.

Figure 13b. Survey biomass for Yellowtail Flounder on Georges Bank in units of thousand metric tons (DFO, NEFSC spring, NEFSC fall, all three are minimum swept area biomass values) or kg/tow (NEFSC scallop, stratified mean catch per tow).

NEFSC Spring Survey

Figure 13c. NEFSC spring survey catch per tow (kg) showing the conversion between the two time series. B2A denotes catches from the Henry B. Bigelow converted to Albatross IV units.

## NEFSC Fall Survey

Figure 13d. NEFSC fall survey catch per tow (kg) showing the conversion between the two time series. B2A denotes catches from the Henry B. Bigelow converted to Albatross IV units.

Figure 13e. Survey biomass coefficients of variation for Yellowtail Flounder on Georges Bank for the three bottom trawl surveys.

DFO

NEFSC Fall

Figure 13f. Survey biomass for Yellowtail Flounder on Georges Bank in units of kg/tow with 95\% confidence intervals from +/- 1.96*stdev (DFO) or bootstrapping (NEFSC spring and NEFSC fall) for years in the assessment.

Figure 14a. Catch of Yellowtail Flounder in weight (kg) per tow for DFO survey. Top left panel shows 2003-2012 average, top right panel shows 2013 catch per tow for comparison.

Figure 14b. Catch of Yellowtail Flounder in weight (kg) per tow for NEFSC spring (top) and NEFSC fall (bottom) surveys. Left panels show previous 10 year averages, right panels most recent data. Note the 2009-2014 survey values were adjusted from Henry B. Bigelow to Albatross IV equivalents by dividing Henry B. Bigelow catch in weight by 2.244 (spring) or 2.402 (fall).

Figure 15a. DFO spring survey estimates of total biomass (top panel) and total number (bottom panel) by stratum area for Yellowtail Flounder on Georges Bank.

NEFSC Spring

Figure 15b. NEFSC spring survey estimates of total biomass (top panel) and proportion (bottom panel) by stratum for Yellowtail Flounder on Georges Bank.

NEFSC Fall

Figure 15c. NEFSC fall survey estimates of total biomass (top panel) and proportion (bottom panel) by stratum for Yellowtail Flounder on Georges Bank.

## DFO

Figure 16a. Age specific indices of abundance for the DFO spring survey including the large tows in 2008 and 2009 (the area of the bubble is proportional to the magnitude). Diagonal red lines denote the 1965, 1975, 1985, 1995, and 2005 year-classes.

## DFO Proportions

Figure 16b. Proportions of age specific indices of abundance for the DFO spring survey including the large tows in 2008 and 2009 (the area of the bubble is proportional to the magnitude). Diagonal red lines denote the 1965, 1975, 1985, 1995, and 2005 year-classes.

## Spring

Figure 16c. Age specific indices of abundance for the NMFS spring survey (the area of the bubble is proportional to the magnitude). Diagonal red lines denote the 1965, 1975, 1985, 1995, and 2005 yearclasses.

## Spring Proportions

Figure 16d. Proportions of age specific indices of abundance for the NMFS spring survey (the area of the bubble is proportional to the magnitude). Diagonal red lines denote the 1965, 1975, 1985, 1995, and 2005 year-classes.

## Fall

Figure 16e. Age specific indices of abundance for the NMFS fall survey (the area of the bubble is proportional to the magnitude). Diagonal red lines denote the 1965, 1975, 1985, 1995, and 2005 yearclasses.

Fall Proportions

Figure 16f. Proportions of age specific indices of abundance for the NMFS fall survey (the area of the bubble is proportional to the magnitude). Diagonal red lines denote the 1965, 1975, 1985, 1995, and 2005 year-classes.

## Scallop

Figure 16g. Age specific indices of abundance for the NMFS scallop survey, note years 1986, 1989, 1999, 2000, and 2008 are not included (the area of the bubble is proportional to the magnitude). Diagonal red lines denote the 1965, 1975, 1985, 1995, and 2005 year-classes.

## Scallop Proportions

Figure 16h. Proportions of age specific indices of abundance for the NMFS scallop survey, note years 1986, 1989, 1999, 2000, and 2008 are not included (the area of the bubble is proportional to the magnitude). Diagonal red lines denote the 1965, 1975, 1985, 1995, and 2005 year-classes.

Figure 16i. Age specific indices of abundance for the recent years of the four surveys, note year 2008 is not included in the scallop plot (the area of the bubble is proportional to the magnitude). The red diagonal line denotes the 2005 year-class.

Figure 16j. Proportions of age specific indices of abundance for the recent years of the four surveys, note year 2008 is not included in the scallop plot (the area of the bubble is proportional to the magnitude). The red diagonal line denotes the 2005 year-class.

Figure 16k. DFO survey catch at age by cohort on log scale. Red lines denote linear regression and blue lines denote $95 \%$ prediction interval for the linear regression. Correlation values are shown in lower right triangle.

Figure 16I. NEFSC spring survey catch at age by cohort on log scale. Red lines denote linear regression and blue lines denote $95 \%$ prediction interval for the linear regression. Correlation values are shown in lower right triangle.

Figure 16m. NEFSC fall survey catch at age by cohort on log scale. Red lines denote linear regression and blue lines denote $95 \%$ prediction interval for the linear regression. Correlation values are shown in lower right triangle.

## Age 1

Age 3

Age 5

Age 2

Age 4

Age 6+

Figure 17a. Standardized catch/tow in numbers at age for the four surveys plotted on natural log scale. The standardization was merely the division of each index value by the mean of the associated time series. Circles denote the DFO survey, triangles the NEFSC spring survey, squares the NEFSC fall survey, and crosses the NEFSC scallop survey.

Figure 17b. Same as Figure 17a except the rescaled index values have been smoothed with a loess fit using $30 \%$ span to more clearly demonstrate similarities or differences among the surveys.

Figure 18a. Median and 2.5\%ile and 97.5\%ile of measured weight (kg) at length by year from the NEFSC spring survey. The horizontal dashed red line denotes the median of the medians.

Figure 18b. Median and 2.5\%ile and 97.5\%ile of measured weight $(\mathrm{kg})$ at length by year from the NEFSC fall survey. The horizontal dashed red line denotes the median of the medians.

Figure 18c. Condition factor (Fulton's $K$ ) for male and female Yellowtail Flounder in the DFO survey.

Figure 19. Trends in relative fishing mortality (catch biomass/survey biomass), standardized to the mean for 1987-2007.

Figure 20. Trends in total mortality $(Z)$ for ages 2, 3, and 4-6 from the four surveys.

## DFO First Age = 3

Figure 21a. Catch curve for DFO survey using age 3 as first age in $Z$ calculation. Top panel shows log of survey catch at age, with symbols denoting ages and colored lines connecting cohorts. Bottom panel shows estimated total mortality rate (Z) from catch curve with $80 \%$ confidence interval by year class of cohort (age 0).

## SPRING First Age = $\mathbf{3}$

Figure 21b. Catch curve for NEFSC spring survey using age 3 as first age in $Z$ calculation. Top panel shows log of survey catch at age, with symbols denoting ages and colored lines connecting cohorts. Bottom panel shows estimated total mortality rate (Z) from catch curve with $80 \%$ confidence interval by year class of cohort (age 0).

## FALL First Age $=\mathbf{3}$

Figure 21c. Catch curve for NEFSC fall survey using age 3 as first age in $Z$ calculation. Top panel shows $\log$ of survey catch at age, with symbols denoting ages and colored lines connecting cohorts. Bottom panel shows estimated total mortality rate (Z) from catch curve with $80 \%$ confidence interval by year class of cohort (age 0).

Figure 22. Fishing mortality rate (ages 4+, top panel), spawning stock biomass ( $m t$, middle panel) and recruitment (millions of age 1 fish, bottom panel) for the TRAC 2013 assessment and updates to the data (see text: Building the Bridge). There are four lines in each panel.

## Split Series

Figure 31a. Age 1 recruitment (millions of fish) estimated by the six VPAs.

Figure 31b. Dotchart of the 2013 age 1 recruitment (millions of fish) for the six VPAs. The filled circles denote the point estimates while the blue crosses denote the rho adjusted values for each run.

Figure 32a. Fishing mortality rate (ages 4-5) estimated by the six VPAs.

Figure 32b. Dotchart of the 2013 fishing mortality rate (ages 4-5) for the six VPAs. The filled circles denote the point estimates while the blue crosses denote the rho adjusted values for each run.

Split Series M02

Single Series M02

Figure 33a. Jan-1 age 1+ biomass estimated by the Split Series M02 VPA (top panel) and by the Single Series M02 VPA (bottom panel) and from the three groundfish surveys in minimum swept area values. The final VPA value uses the geometric mean of the previous ten years for the age 1 recruitment.

Split Series M04

Single Series M04

Figure 33b. Jan-1 age 1+ biomass estimated by the Split Series M04 VPA (top panel) and by the Single Series M04 VPA (bottom panel) and from the three groundfish surveys in minimum swept area values. The final VPA value uses the geometric mean of the previous ten years for the age 1 recruitment.

Split Series M0409

Single Series M0410

Figure 33c. Jan-1 age 1+ biomass estimated by the Split Series M0409 VPA (top panel) and by the Single Series M0410 VPA (bottom panel) and from the three groundfish surveys in minimum swept area values. The final VPA value uses the geometric mean of the previous ten years for the age 1 recruitment.

Figure 34. Point estimates of terminal year SSB (mt) and F (ages 4+) with $80 \%$ confidence intervals (horizontal and vertical lines) and rho adjusted estimates of SSB and F (triangles) for the six combinations of VPAs. The horizontal dashed line denotes $F_{r e f}=0.25$.

Figure 35a. Stock recruitment relationship from the Split Series M02 VPA and the Single Series M02 VPA. The number denotes year-class (year of SSB and year when recruitment was age 0). The triangle denotes the spawning stock biomass in 2013 (the 13 label shows the geometric mean of the recent 10 years of recruitment).

Figure 35b. Stock recruitment relationship from the Split Series M04 VPA and the Single Series M04 VPA. The number denotes year-class (year of SSB and year when recruitment was age 0). The triangle denotes the spawning stock biomass in 2013 (the 13 label shows the geometric mean of the recent 10 years of recruitment).

Figure 35c. Stock recruitment relationship from the Split Series M0409 VPA and the Single Series M0410 VPA. The number denotes year-class (year of SSB and year when recruitment was age 0). The triangle denotes the spawning stock biomass in 2013 (the 13 label shows the geometric mean of the recent 10 years of recruitment).

Figure 36a. Estimated age 1 recruitment in millions of fish (denoted by bars) and spawning stock biomass in thousands of metric tons (denoted by solid line) by year-class (recruitment) or year (SSB) from the Split Series M02 VPA. The 2013 recruitment year-class is the geometric mean of the previous ten years.

Figure 36b. Estimated age 1 recruitment in millions of fish (denoted by bars) and spawning stock biomass in thousands of metric tons (denoted by solid line) by year-class (recruitment) or year (SSB) from the Split Series M04 VPA. The 2013 recruitment year-class is the geometric mean of the previous ten years.

Figure 36c. Estimated age 1 recruitment in millions of fish (denoted by bars) and spawning stock biomass in thousands of metric tons (denoted by solid line) by year-class (recruitment) or year (SSB) from the Split Series M0409 VPA. The 2013 recruitment year-class is the geometric mean of the previous ten years.

Single Series M02

Figure 36d. Estimated age 1 recruitment in millions of fish (denoted by bars) and spawning stock biomass in thousands of metric tons (denoted by solid line) by year-class (recruitment) or year (SSB) from the Single Series M02 VPA. The 2013 recruitment year-class is the geometric mean of the previous ten years.

Single Series M04

Figure 36 e. Estimated age 1 recruitment in millions of fish (denoted by bars) and spawning stock biomass in thousands of metric tons (denoted by solid line) by year-class (recruitment) or year (SSB) from the Single Series M04 VPA. The 2013 recruitment year-class is the geometric mean of the previous ten years.

Figure 36f. Estimated age 1 recruitment in millions of fish (denoted by bars) and spawning stock biomass in thousands of metric tons (denoted by solid line) by year-class (recruitment) or year (SSB) from the Single Series M0410 VPA. The 2013 recruitment year-class is the geometric mean of the previous ten years.

Figure 37a. Probability the fishing mortality rate in 2015 is greater than $F_{\text {ref }}=0.25$ for a range of catch values in 2015 and six projection scenarios with no adjustment to the starting population size.

Figure 37b. Probability the fishing mortality rate in 2015 is greater than $F_{\text {ref }}=0.25$ for a range of catch values in 2015 and six projection scenarios with the starting population size rho adjusted.

Figure 38a. Relative change in median adult Jan-1 biomass from 2015 to 2016 for a range of catch values in 2015 and six projection scenarios with no adjustment to the starting population size.

Figure 38b. Relative change in median adult Jan-1 biomass from 2015 to 2016 for a range of catch values in 2015 and six projection scenarios with the starting population size rho adjusted.

Figure 39a. Probability adult Jan-1 biomass will not decline (top panel) or will increase by at least 10\% (bottom panel) from 2015 to 2016 for a range of catch values in 2015 and six projection scenarios with no adjustment to the starting population size.

Figure 39b. Probability adult Jan-1 biomass will not decline (top panel) or will increase by at least 10\% (bottom panel) from 2015 to 2016 for a range of catch values in 2015 and six projection scenarios with the starting population size rho adjusted.

## Split Series M02

Figure 40a. Comparison of the population abundance at age distributions for the Split Series M02 VPA among the average of 1973-2012, 2013, and that expected when the population is fished in equilibrium at $F_{\text {ref }}=0.25$. The equilibrium numbers at age 1 in the top panel are set equal to the average for years 19732012. The bottom panel shows the proportions at age instead of numbers.

## Split Series M04

Figure 40b. Comparison of the population abundance at age distributions for the Split Series M04 VPA among the average of 1973-2012, 2013, and that expected when the population is fished in equilibrium at $F_{\text {ref }}=0.25$. The equilibrium numbers at age 1 in the top panel are set equal to the average for years 19732012. The bottom panel shows the proportions at age instead of numbers.

## Split Series M0409

Figure 40c. Comparison of the population abundance at age distributions for the Split Series M0409 VPA among the average of 1973-2012, 2013, and that expected when the population is fished in equilibrium at $F_{\text {ref }}=0.25$. The equilibrium numbers at age 1 in the top panel are set equal to the average for years 19732012. The bottom panel shows the proportions at age instead of numbers.

## Single Series M02

Figure 40d. Comparison of the population abundance at age distributions for the Single Series M02 VPA among the average of 1973-2012, 2013, and that expected when the population is fished in equilibrium at $F_{\text {ref }}=0.25$. The equilibrium numbers at age 1 in the top panel are set equal to the average for years 19732012. The bottom panel shows the proportions at age instead of numbers.

## Single Series M04

Figure 40e. Comparison of the population abundance at age distributions for the Single Series M04 VPA among the average of 1973-2012, 2013, and that expected when the population is fished in equilibrium at $F_{\text {ref }}=0.25$. The equilibrium numbers at age 1 in the top panel are set equal to the average for years 19732012. The bottom panel shows the proportions at age instead of numbers.

## Single Series M0410

Figure 40f. Comparison of the population abundance at age distributions for the Single Series M0410 VPA among the average of 1973-2012, 2013, and that expected when the population is fished in equilibrium at $F_{\text {ref }}=0.25$. The equilibrium numbers at age 1 in the top panel are set equal to the average for years 1973-2012. The bottom panel shows the proportions at age instead of numbers.

Figure 41. Historical retrospective analysis of Georges Bank Yellowtail Flounder assessments from this and the previous eight TRAC Split Series VPAs with M=0.2 for age 4+ fishing mortality (top panel), spawning stock biomass (middle panel), and age 1 recruitment (lower panel). Note there are two lines plotted for TRAC 2009 (terminal year 2008), the "Including" and "Excluding" formulations.

## 2013 Catch at Age

Figure 42. Catch ( $m t$ ) at age in 2013 projected from the previous two TRAC assessments compared to the 2013 values observed in this assessment. The three projections are from the Split Series deterministic table in their respective assessment documents. The 2012 TRAC projections assumed $F$ would be Fref=0.25, while the 2013 TRAC projections assumed the full quota of 500 mt would be caught. The total catch in the three projections were 171, 836, and 499 mt , respectively, while the actual total catch was 218 mt.

## \% Exploitation Rate (YPR/TSBPR)

Figure 43. Contours of equal percent exploitation rate (defined as the yield per recruit divided by the total stock biomass per recruit) for combinations of the natural mortality rate (M) and fishing mortality rate (F). The red circles and blue triangles denote $F_{40 \%}$ and $F_{0.1}$ computed for select values of $M$.

## \% Exploitation Rate (YPR/TSBPR)

Figure 44. Contours of equal percent exploitation rate (defined as the yield per recruit divided by the total stock biomass per recruit) for combinations of the natural mortality rate ( $M$ ) and fishing mortality rate ( $F$ ). The light blue polygon is provided as a demonstration of possible combinations of $M$ and $F$ that could be used to define the exploitation rate to be used in the empirical approach (see text for details). The diagonal red dashed line denotes a constant total mortality rate of 1.05.

## APPENDIX

The table below was kindly initiated by Tom Nies (NEFMC). It summarizes the performance of the management system. It reports the TRAC advice, TMGC quota decision, actual catch, and realized stock conditions for Georges Bank Yellowtail Flounder.
(1) All catches are calendar year catches
(2) Values in italics are assessment results in year immediately following the catch year; values in normal font are results from this assessment

| TRAC | Catch Year | TRAC Analysis/Recommendation |  | TMGC Decision |  | Actual Catch ${ }^{(1)} /$ Compared to Risk Analysis | Actual Result ${ }^{(2)}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | Amount | Rationale | Amount | Rationale |  |  |
| $1999{ }^{1}$ | 1999 | (1) $4,383 \mathrm{mt}$ <br> (2) $6,836 \mathrm{mt}$ | Neutral risk of exceeding Fref <br> (1)VPA <br> (2)SPM | NA | NA | $4,441 \mathrm{mt} / 50 \%$ risk of exceeding Fref (VPA) | Exceeded Fref (2.6X) |
| 2000 | 2000 | 7,800 mt | Neutral risk of exceeding Fref | NA | NA | 6,895 mt/About 30\% risk of exceeding Fref | Exceeded Fref (3.6X) |
| 2001 | 2001 | 9,200 mt | Neutral risk of exceeding Fref | NA | NA | $6,790 \mathrm{mt} / \mathrm{Less}$ than $10 \%$ risk of exceeding Fref | Exceeded Fref (3.8X) |
| 2002 | 2002 | 10,300 mt | Neutral risk of exceeding Fref | NA | NA | 6,100 mt/Less than 1\% risk of exceeding Fref | Exceeded Fref (2.5X) |

Transition to TMGC process in following year; note catch year differs from TRAC year in following lines

| 2003 | 2004 |  | No confidence in projections; status quo catch may be appropriate | 7,900 mt | Neutral risk of exceeding Fref, biomass stable; recent catches between 6,100$7,800 \mathrm{mt}$ | 6,815 mt | F above 1.0 Now F $=1.94$ Age 3+ biomass decreased $53 \%$ 04-05 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 2004 | 2005 | 4,000 mt | Deterministic; other models give higher catch but less than 2004 quota | 6,000 mt | Moving towards Fref | 3,851 mt | $F=1.37$ <br> Age 3+ biomass decreased 5\% 05-06 <br> Now F $=1.39$ <br> Age 3+ biomass decreased 39\% 05-06 |
